For angular cheilitis or denture stomatitis nystatin may be prescribed as cream (100,000 IU/g) three times daily for 10–14 days (Lombardi and Ouanounou, 2020). Topical miconazole (gel or cream) is also effective against OC, especially in those cases of denture stomatitis. Miconazole gel 2% can be applied to the fitting surface of the denture, two to three times a day, for 2 or 3 weeks. It could also be applied as a lacquer to dentures, once a week to dentures for 3 weeks (Williams and Lewis, 2011; Bandara and Samaranayake, 2019; Telles et al., 2017). Miconazole cream (2%) is as well a good therapeutical option for treating angular cheilitis, applied directly in the lesions two times a day for 2–3 weeks (Williams and Lewis, 2011; Lombardi and Ouanounou, 2020). It is important to consider that miconazole, even topically, may interact with warfarin and should also be avoided in pregnancy and patients with porphyria (Lombardi and Ouanounou, 2020; Quindos et al., 2019). Other agents as ketoconazole, clotrimazole, itraconazole or fluconazole could also be used topically (Lombardi and Ouanounou, 2020). Another topical antifungal is the Gentian violet solution. It is used in doses of 1.5 mL twice a day. This antifungal can cause oral ulcers, skin irritation and staining (Lombardi and Ouanounou, 2020).

Systemic treatment

In those cases where there is a widespread, recurrent, or refractory OC, systemic antifungals such as fluconazole or itraconazole should be used (Bandara and Samaranayake, 2019). Since ketoconazole causes hepatotoxicity, several drug interactions and potential teratogenicity, its clinical use has been very limited, and it should not be the first choice for treating OC (Lewis and Williams, 2017; Lombardi and Ouanounou, 2020). In the same line, as said before, it should be reminded when prescribing these

Table 5 Topical and systemic antifungal therapy most used in oral candidiasis.

Drugs (Class)	Dose
Nystatin (Polyene)	• Oral suspension, 100,000 IU/mL, 4–6 mL, four times daily, during 2–3 min for 7–14 days. • Pastilles (100,000 IU, four times daily) for 7–14 days.
Amphotericin B (Polyene)	• Cream (100,000 U/g), three times daily for 10–14 days. • Oral suspension (100 mg/mL), 100–200 mg for 14 days. • Lozenge (10 mg), for 14 days. • Cream, for 14 days.
Miconazole (Imidazole)	• Gel (2%), two to four times a day for 2–3 weeks. • Lacquer, once a week to dentures for 3 weeks. • Cream (2%), two times daily for 2–3 weeks.
Ketoconazole (Imidazole)	• Cream (2%), two to three times daily for 14–28 days. • Oral tablets, 200–400 mg, four times daily for 14 days.
Clotrimazole (Imidazole)	• Troches (10 mg), five times daily for 14 days. • Solution (1%), 5 mL, four times daily for 14 days. • Cream (1%), two to three times daily for 21–28 days.
Fluconazole (Triazole)	• Oral capsules, initial dose of 200 mg followed by 100 mg daily for 1–2 weeks.
Itraconazole (Triazole)	• Oral capsules, initial dose of 200 mg, three times daily for 3 days, followed by 100 mg for 11 days for refractory candidiasis. • Oral capsules, initial dose of 100 mg, four times daily for 14 days for initial candidiasis. • Oral suspension, 100–200 mg, two times daily for 7–14 days.
Voriconazole (Triazole)	• Oral, for refractory OC, at a dose of 200 mg two times daily for 28 days.
Posaconazole (Triazole)	• Oral suspension, for refractory candidiasis, 400 mg two times daily for 3 days, followed by 400 mg 4 times daily for 25–28 days. • For initial cases, 100 mg two times on the first day, followed by 100 mg four times daily for the next 13 days.

drugs that azole antifungal agents (including itraconazole and fluconazole) interact with warfarin (Lewis and Williams, 2017). Fluconazole is the most widely used, and it is frequently dispensed as oral capsules, in an initial dose of 200 mg followed by 100 mg a day for 1–2 weeks. Itraconazole should be chosen for treating refractory candidiasis. Other systemic antifungal drugs are voriconazole, isavuconazole and posaconazole. These new triazoles along with echinocandins are promising alternatives therapeutic options (Lombardi and Ouanounou, 2020; Quindos et al., 2019). Although the efficacy of certain antifungals such as nystatin, amphotericin B, clotrimazole, miconazole, ketoconazole, itraconazole has been demonstrated, there are studies that have shown how fluconazole is superior to other antifungals. As with antibiotics, there is also resistance among *Candida* species, which can also be a public health problem (Fang et al., 2020).

Table 4 summarizes systemic treatments for other fungal infections that may affect the oral cavity less frequently.

Adjunctive agents: Sialogogues, chlorhexidine, probiotics

There are other adjunctive therapeutic options that may contribute to *Candida* eradication. In those patients with reduced salivary flow and residual glandular capacity, the use of sialogogues may be assessed. This treatment aims to increase salivary flow and, therefore, the fungicidal power of saliva. Systemic sialogogues as pilocarpine have several side effects, and should be avoided in patients with glaucoma, hypertensive patients or those with uncontrolled asthma (Lombardi and Ouanounou, 2020).

Oral rinses with chlorhexidine gluconate (0.12%) for 1 min 2 times a day for 2 weeks can be used as a preventive measure in recurrent OC (Lombardi and Ouanounou, 2020). Other mouthwashes with antifungal activity as triclosan, or essential oil formulations (usually containing natural plant extracts as eucalyptol, thymol or bioflavonoids) may also be used. In cases of denture stomatitis, if the denture has metal components chlorhexidine 0.2% should be used for its cleanse (Bandara and Samaranayake, 2019).

Since there is an increasing resistance to the antifungal therapies, alternative treatments, as probiotics have emerged (Ribeiro et al., 2020; Shenoy and Gottlieb, 2019). Its usefulness in the treatment of OC is due to enhance immune response and mucosal barrier and reduce pathogens. In addition, they adhere to epithelial cells and mucus and can therefore reduce adhesion to the surfaces of fungal microorganisms. They also produce inhibition of *Candida* producing certain metabolites or competing for adhesion sites preventing *Candida* colonization and growth. Different studies have proven their positive effects as a treatment for OC, decreasing the levels of yeast and increasing IgA (Hoare et al., 2017; Ribeiro et al., 2020; Shenoy and Gottlieb, 2019). Different species of the genus *Lactobacillus* and *Bifidobacterium* may be a good option especially in elderly patients, or as a adjuvant treatment to antifungal therapies (Ribeiro et al., 2020; Shenoy and Gottlieb, 2019). There are studies that have used *B. longum*, *B. bifidum*, *L. rhamnosus*, *L. reuteri*, *L. casei*, *L. acidophilus*, *L. bulgaricus*, *S. thermophilus* or *Propionibacterium freudenreichii* to reduce *Candida* species levels in the oral cavity and dentures, and the oral pain produced by OC (Hoare et al., 2017; Shenoy and Gottlieb, 2019). However, probiotics have not shown superiority to the usual treatments for OC such as nystatin. Therefore, scientific evidence today shows their usefulness more in prevention than in the treatment of OC (Shenoy and Gottlieb, 2019).

Intro

The mouth is an organ involved in several activities, mainly respiration, phonation, alimentation, and interpersonal contacts. The anatomic bases of these functions are supported by different tissues providing structural and mechanical specificities. The surface of these tissues and their interfaces offer distinct barriers between the oral cavity and the internal milieu, as well as varied microenvironments possibly hosting microbiota. These interactions are not static but rather depend on the influence of flows in the mouth corresponding to the function of this complex organ: air for breathing and talking; liquids, solids, nutrients, and other molecules while feeding; microorganisms during interpersonal contacts or vectorial contamination by food or hands, among others. It is thus important to consider that the mouth can be contaminated by some substances or organisms, while it will not be properly infected by the latter. For instance, in taxonomic studies using 18s RNA gene sequencing to detect parasites or fungi in different oral sites, results can be filtered to exclude species of organisms coming from the food, like vegetables and animals. This obvious example questions us about the relevance of repeated detection, even if in high abundance: do we measure frequent habits of seeding the mouth with some microorganisms or do we evaluate their capacity to colonize this environment?

To define a true infection, the durability of the interaction between the host and the microorganism must be evaluated in the absence of any recontamination. Oral hygiene is a Sisyphean task that leads to the—often daily—disorganization of microbial communities. The main goal of this strategy in the dental environment is to hinder the maturation of biofilms to dental plaque and, later, to tartar. Supragingival accumulation of bacteria can initiate the formation of cavities. Subgingival calculi and plaque cause inflammation (gingivitis) and can lead to irreversible bone loss (periodontitis). In these biofilms are detected in vast majority bacteria, but it is now widely accepted that other infectious agents are present in the oral cavity, in particular eukaryotes and viruses, and that they may affect other tissues, like the mucosa. Fungal infections are not uncommon and oral candidiasis is a pathologic manifestation of the colonization of the mouth mucosae by *Candida albicans*. Other fungal genera are also frequently detected in the human periodontal sulcus, like *Malassezia*, *Aspergillus*, *Penicillium*, and *Rhodotorula*, while their role in periodontitis is still to be deciphered (reviewed in Karkowska-Kuleta et al., 2021).

Parasites—motile eukaryotic microorganisms—are also detected in the mouth: those for which this entry route is a dead-end (for instance, *Plasmodium falciparum* and *Amoeba proteus*), those that travel through it when contaminating the human host via an oral route (like *Entamoeba histolytica*, *Taenia solium*, and *Toxoplasma gondii*), and those that will settle a durable infection within the human host (*Leishmania* spp., *Trichomonas tenax*, and *E. gingivalis*). This chapter will focus on the latter group.

Amoebae in periodontitis

The parasites

Discovery

Amoebae are eukaryotic unicellular organisms with a characteristic motility. They adhere to the substrate, emit one or several pseudopods and drag the rest of the cell body onwards. Pseudopods are cytoplasm projections delimited by the plasma membrane, budding in the direction of the movement. This type of mobility has been described since the middle of the 18th century and the mere name of amoeba reflects the ability to move, observed in free-living amoebae, i.e., amoebae that do not need a host to survive and divide (Rösel von Rosenhof, 1755). It is noteworthy that the then-recent improvement of microscopes allowed to observe the deformations of these “big” eukaryotic cells, which probably increased the perception of their active movements as compared to flagellated protozoans or bacteria.

Amoebae were detected in association with humans as early as the middle of the 19th century: in the dental plaque (Fig. 1), with no mention of their possible involvement in pathogenic processes (Gros, 1849):

«Au milieu des productions du tartre des dents, on voit des vibrios, une sorte de végétation qui est quelque fois très régulière; mais on n'avait pas encore mentionné les vésicules que nous avons représentées Pl. VI. B. Ces vésicules ont un mouvement si lent et si obscur qu'il faut en être averti pour remarquer qu'elles prennent toutes les formes, par une extension et contraction amoebéenne, laissant toujours voir à l'intérieur des globules qui semblent se déplacer un peu, et être l'analog de ce que nous connaissons chez de certains infusoires soi-disant polygastriques. Leur origine, leur rôle et leur fin sont ignorés. Elles se trouvent surtout à la face interne des dents. Est-ce encore une génération spontanée?»

In the middle of the production of tartar of the teeth, vibrios can be observed, a sort of vegetation that is sometimes very regular; but were never mentioned before the vesicles we represented Pl. VI. C. These vesicles have such a slow and obscure motion that one must be aware of it to note that they can take any forms, by an amoeban extension and contraction. Inside of them, some globules are always visible—they seem to move a bit—and seem to be the analog to what is known in some infusoria, so-called polygastric. Their origin, their role, and their aim are ignored. They are found in particular on the internal face of the teeth. Is this again a spontaneous generation? (translation from the author).

In the era preceding Pasteur's and Koch's discoveries—though contemporary of John Snow's striving research on cholera and thus of the beginnings of modern epidemiology—these amoebae from clinical samples were not assumed or suspected to be pathogenic. Furthermore, periodontitis was such a common condition that its cause was not especially sought: it was rather considered part of the normal aging process.

The end of the 19th century was marked by the emergence and maturation of the concept of infectious disease, and an infectious etiology for all ailments was investigated. In this quest, *E. histolytica* was found to cause dysentery (Lösch, 1875). This close-related organism to *E. gingivalis* drew attention to the possible link between the oral parasite and periodontitis (Kartulis, 1893):

Der Substanzverlust entspricht darnach einem echten Knochengeschwür. Die Amöben liegen gewöhnlich am Grunde des Geschwüres, und auch dies erinnert an Bilder von dysenterischen Geschwüren. [...] Darüber, ob Amöben schliesslich Entzündung, beziehungsweise Verschwärung oder Abscessbildung bedingen können, möchte ich auf die Schlussfolgerungen verweisen, welche in meinen Arbeiten über die Aetiologie der Dysenterie, beziehungsweise der Leberabscesse zu finden sind.

The loss of substance corresponds to a real bone ulcer. The amoebae are usually at the base of the ulcer, and this too is reminiscent of images of dysenteric ulcers. [...] Regarding whether amoeba can ultimately cause inflammation, either by exacerbating or producing abscesses, I would like to refer to the conclusions that can be found in my work on the etiology of dysentery and liver abscesses. (translation from the author).

Fig. 1 *Amoeba gingivalis*, first description of *Entamoeba gingivalis*. Figure from Table VI C in Gros G (1849) Fragments d'helminthologie et de physiologie microscopique. *Bulletin de la Société Impériale des Naturalistes de Moscou* 22 : 549–573.

Beside this injunction to consider the association between *E. gingivalis* and periodontitis, the lack of rigorous epidemiological studies impeded to formerly conclude and thus to validate the first Koch's postulate, leaving the field with a blurry message about the etiology of the disease (Barrett, 1914):

It is well known with what persistent difficulties the dental profession has labored in connection with the condition usually spoken of as pyorrhea alveolaris; nor is there occasion here to go into details as to the various views which have been presented as to its etiology and the methods by which it is to be handled in treatment. Pyorrhea alveolaris has always been regarded as a form of bacterial infection in which local irritative conditions—such as the presence of tartar or the downward growth of the enamel organ in form of Hertwig's sheath—are thought to play at least a predisposing part, if no more, and in which systemic faults have very commonly by variously been looked upon as etiological factors by different writers at different times. [...].

From this standpoint and from a general interest in the fact that the studies of the protozoan parasitology of the mouth—a location appreciably suited to the protozoa from the viewpoint of its conditions of moisture, temperature, provision of appropriate food material and openness to the chances of infestation—have been relatively infrequent and unsystematized, the present study was undertaken. It seemed entirely probable that not only forms of rhizopods, such as the amoebae described by Kartulis and by Prowazek and others, in a comparatively limited number of cases, but possibly also flagellates and ciliates might be accommodated in this part of the body, and that those at least which are not mere surface habitants, but actually penetrate into the tissues, might in some of the inflammatory conditions of the mouth, particularly in the chronic ulcerative forms, in analogy with the chronic ulcerations due to dysenteric amoebae, be of pathogenic importance.

In this study, the 46 samples from periodontal pockets contained amoebae, as detected by microscopy (Barrett, 1914). Soon after this, a study detected *Entamoeba buccalis* in 199 of the 200 evaluated samples (Bass and Johns, 1914). The only sample in which amoebae were not detected came from a patient who recently used ipecac, whose root is used for emetine extraction. Ipecac root and emetine have been used to cure amoebic dysentery and liver abscess (Rogers, 1912), and have been shown to be effective against both inflammation and amoebae in the context of periodontitis (Barrett, 1914; Bass and Johns, 1914). However, this was not a formal demonstration for causation, and the specificity of the drug was soon questioned (Howitt, 1925). Reports about emetine cardiotoxicity changed the perception of the risk-benefit ratio (Chopra and Ghosh, 1922; Dale, 1915) and led to give up its use against amoebae.

This scientific odyssey about *E. gingivalis* involvement in periodontitis was not stopped by this failed attempt to indirectly demonstrate its etiologic role. Back to the first Koch's postulate, the association of the parasite with the disease was legitimately questioned: these amoebae are not rarely detected in "healthy" samples {14/46 = 30.4%; (Chiavaro, 1914)}. This was proposed to be due to common and recurrent contamination sources from the environment, also making the cure of deep pockets more fastidious (Bass and Johns, 1914):

As long as the lesion is not healed up it naturally offers favorable soil for reinfection. The disease is almost universal, and, therefore, chances of getting infection from others must exist almost daily.

To confirm the second and third Koch's postulates, microorganism culture and an adequate animal model are needed. However, *E. gingivalis* culture, though feasible (Howitt, 1925), is uneasy and polyxenic. Even if experimental periodontitis was developed in canine models, it was impossible to exclude the bacterial microbiota as the cause or a necessary adjuvant for the pathophysiology (Kofoid et al., 1929).

The stammering field of infectiology had then exhausted its resources to study the possible causative link between periodontitis and the presence of *E. gingivalis* or other microorganisms. The most convincing model for periodontitis was then non-infectious, and microorganisms were mainly thought to be opportunistic or saprophytic (Belding and Belding, 1933; Bruske, 1928). This status quo was maintained until new methods allowed a deeper characterization of the microbiota in parallel to the rise of new concepts about disease causation (Hill, 1965).

Cellular characteristics

Amoebae from the genus *Entamoeba* possess a cystic form in their life cycle allowing them to survive environmental stresses like high oxygen pressure from the air and desiccation and thus to be transmitted from host to host. Though early reports described the presumed cysts of *E. gingivalis* (Chiavaro, 1914; Craig, 1916; Smith and Barrett, 1915), it is now believed to be the only cyst-deprived species of the genus *Entamoeba*, existing only as trophozoites, its vegetative form. Several hypotheses can be formulated. First, transmission may be more direct than thought and oxidative stress may not be sufficient to kill the vegetative form of the parasite, the trophozoite. Second, interaction with bacteria could lead to higher resistance to oxidative stress, like for its close relative *E. histolytica* (Varet et al., 2018). Finally, cysts may not be produced in all individuals and in all the niches where trophozoites are found, meaning that they might not be found in some dental plaque samples in humans, where they are sought.

The genus *Entamoeba* comprises amoebae that emit a unique lobose (blunt) pseudopodia. The cells constantly deform, allowing them to displace and to feed. They are variable in size: in 1915, a review mentioned that, according to the sources, parasites could measure from 6 to 40 µm (Smith and Barrett, 1915). The intracellular composition of the parasite has also been described very early (reviewed in Howitt, 1925), mentioning its large spherical nucleus and intracytoplasmic food vacuoles. These food vacuoles are formed by the phagocytosis of human cells or microbes.

Genetic diversity

Before the emergence of genetic methods, morphological and physiological criteria of microorganisms were used to identify species. The amoebae of the oral sphere face different environments, from crevicular fluid or saliva to solid tartar deposits, from health-related microbiota to periodontitis-linked microenvironments, and finally are observed in different conditions for microscopy. It is thus expected to have strong variations in shape, composition, motility, and size, which led to the propose the existence of several species: *Amoeba gingivalis* (Gros, 1849), *Amiba buccalis* (Steinberg, 1862), *Amoeba dentalis* (Grassi, 1879), *Entamoeba buccalis* (Prowazek, 1904), and *Entamoeba kartulisi* (Kartulis, 1893). These were soon reunited as the same species by Smith and Barrett (1915), and confirmed in a close to consensual manner (Craig, 1916).

Later, phylogenetic relationships in the *Entamoeba* genus have been studied by riboprinting and revealed two ribodemes for the *E. gingivalis* species, confirming some genetic differences exist (Clark and Diamond, 1997). These isolates were however very closely related, and more similar between them than with any other isolate from other *Entamoeba* species. Further analyzes showed that single nucleotide polymorphisms exist in the 18S rRNA gene for different *E. gingivalis* isolates and allowed, together with low-stringency single specific primer PCR (LSSP-PCR), the identification of 4 different strains in addition to the reference strain (ATCC30927) (Cembranelli et al., 2013). Interestingly, these five strains belong to the same *E. gingivalis* subtype (ST1), as opposed to the newly characterized “kamaktli variant,” or *E. gingivalis* ST2 (Garcia et al., 2018b). It is noteworthy that the sequencing of the rRNA:18S-ITS1-5.8S-ITS2 shows a similarity between the subtypes that is lower than this observed between the species *E. dispar* and *E. histolytica*. Furthermore, a differential link between the subtypes and the periodontal health status has been proposed but is still to be investigated (Garcia et al., 2018a; Zaffino et al., 2019).

It is noteworthy that the full *E. gingivalis* genome is still not available.

Entamoeba gingivalis and periodontal diseases

Epidemiology

Periodontitis is characterized by irreversible bone loss, leading to clinical attachment loss and to the formation of periodontal pockets. The subsequent retraction of gingival tissues will result in a visible marginal recession, which testifies for an older bone loss. Beside the irreversible loss caused by periodontitis, the inflammation and gum swelling in gingivitis is defined as reversible, without bone loss and deep pockets. Following this model, it was early questioned if the transition from gingivitis to periodontitis was due to a change in the microbiota and, more precisely, to the colonization by a pathogen, as opposed to a model in which gingivitis would be an initial, lower-grade periodontitis with undetectable irreversible damage, though possibly existent.

The development of genetics-based diagnostic methods, which are less impacted by the user's subjectivity and technical skills, allowed the reassessment of the link between *E. gingivalis* and periodontitis. By PCR, the prevalence of the amoeba in periodontal pockets is 76.9% (95%-CI: 71.5%–81.7%), while it is 29.6% (95%-CI: 24.4%–35.3%) in healthy sulci, giving a risk ratio of 3.96 (95%-CI: 1.57–9.98) by meta-analysis (Martin-Garcia et al., 2021). The ST1 was subtype more prevalent (70.6%, 95%-CI: 65.0%–76.2%) than ST2 (43.9%, 95%-CI: 35.5%–52.4%) in periodontal pockets, though their risk ratios are equal: 3.30 (95%-CI: 1.27–8.55) for ST1 and 3.30 (95%-CI: 0.42–26.03) for ST2. In parallel, the subtypes might exhibit a different prevalence in gingivitis (Garcia et al., 2018a).

Pathophysiology

Besides the correlation between parasite presence and disease, the possible virulence of *E. gingivalis* was based on its ability to phagocytose human cells and bacteria in plaque smears (Child, 1926). Most of the virulence traits of *E. gingivalis* were suspected due to the vicinity of the morphologically indistinguishable pathogenic species *E. histolytica*. Recent studies have shown that *E. gingivalis* can provoke inflammation and tissue destruction in vitro (Bao et al., 2020, 2021). The mechanisms leading to these effects could be conserved with *E. histolytica* and are still to be investigated.

Conclusive remarks: Therapeutic management

Diagnosis of periodontal disease is based on the clinical detection of irreversible damage. As *E. gingivalis* is strongly correlated with periodontal diseases, it can be hypothesized that it is a good indicator of ongoing pathogenic processes. Thus, clinical and microbiological diagnosis may not be equivalent, and the detection of amoebae may allow the early detection of periodontally compromised sites.

Prophylactic strategies against the parasites are difficult to implement since both its life cycle and its role in the pathophysiology of the disease are not defined. The consensually assumed absence of a cystic stage reminds us of the possible inadequacy of the conclusions extrapolated from *E. histolytica*. However, treatment using emetine led to the clearing of parasites in humans (Barrett, 1914; Bass and Johns, 1914), while metronidazole is currently used with this aim by some dentists (Bonner et al., 2013) and was shown effective against *E. gingivalis* (Eloufir et al., 2014). As metronidazole is often used to target anaerobic bacteria, it may already take part into clearing *E. gingivalis* from periodontal pockets.

Trichomonads in periodontitis

The parasites

Discovery

Trichomonads are anaerobic flagellated protists. The members of the genus *Trichomonas* have a typical pear shape with a broad front end and a finer tail, as described for the species *Trichomonas tenax* in 1773 by Otto Friedrich Müller, who named it “*Cercaria tenax*” (Müller, 1773):

Membranous *Cercaria*, well-defined and somewhat more solid anterior part, rear-end three times as short. Substantially bigger than *Monas lens*. Transparent, inverted egg-shaped membrane with a neat and strong front; it ends as a sharp at its posterior extremity or in a very short tail. No internal apparatus. Moves in all the directions with quick turns [...] In infusion of tooth dirt within 4 days. (Translation from Latin by the author).

Donné proposed in 1836 to give the name “*Trico-monas vaginale*” to the microbes found in the purulent vaginal discharge who are close to “*Monas*” because of their “trunk,” and to “*Tricodes*” because of their cilia (Donné, 1836) (Fig. 2), later respelled “*Trichomonas vaginalis*.” For decades, several species of *Trichomonas* were suspected to live in the mouth, as reported later (Dobell, 1939). The consolidation of the *Trichomonas* genus in man, with three species, each one unique in its niche as we know now (*T. tenax* in the mouth, *T. vaginalis* in the urogenital tract, *T. hominis* in the intestine) was fixed by Wenrich (1947).

Fig. 2 *Cercaria tenax* (Müller, 1786), with a “stronger front” (A) and a “small tail” (B). Reproduction by Dobell C (1939) The common flagellate of the human mouth, *Trichomonas tenax* (O.F.M.): Its discovery and its nomenclature. *Parasitology* 31(1) : 138–146.

Cellular characteristics

The life cycle of the parasite *T. tenax* is still undeciphered. Beside the pear-shaped trophozoite form commonly found in culture, a rounded, an amoeboid, and a pseudocyst form were described when interacting with cells (Ribeiro et al., 2015). Interestingly, a pseudocyst form also exists in the close-related *T. vaginalis* species, which is devoid of a typical cyst wall, undergoes membrane deformation, and causes strong pathogenic effects (Afzan and Suresh, 2012; Dias-Lopes et al., 2017). An additional cyst-like structure has been produced in vitro and detected in clinical samples (Berl et al., 2019). They possess a thick electron-dense layer consistent with a cyst wall and are more resistance to chlorination than trophozoites. Cyst-like structures could play a role in the non-sexual transmission of the parasite (Pereira-Neves and Benchimol, 2008). The existence of such structures in *T. tenax* is still questioned.

As the parasite *T. vaginalis* is more extensively studied, it is tempting to speculate about the biology of *T. tenax* based on the data obtained with the close-related species from the feminine sexual tract. However, the environments in which they evolve exhibit differences and axenic trophozoite cultures are available since 1962 (Diamond, 1962). Thus, caution must be taken when extrapolating from the parasite from the feminine sexual tract and fundamental research using *T. tenax* should be promoted.

The parasite *T. tenax* revealed it has a fibronectin-like surface molecule probably involved in adherence to microbes and to host cells (Ribaux et al., 1983). It also harbors proteases (Bozner and Demes, 1991a,b; El Sibaei et al., 2012; Yamamoto et al., 2000) and hemolysins (Nagao et al., 2000), which may be involved in target lysis. Virulence of *T. tenax* is now undoubted and the parasite is cytotoxic towards several types of cells (Ribeiro et al., 2015). However, the mechanisms involved in the interaction with host cells still remain to be elucidated.

Genetic characteristics

Only one species of trichomonads is suspected to colonize the human mouth since the reunification of the different candidate species in 1939 (Dobell, 1939). The first full genome sequence of *T. tenax* has been recently released (accession number PRJEB22701) and is still to be assembled and annotated. The same research team already published the link between *T. tenax* genetic background and the severity of periodontitis in the same geographical area (Benabdelkader et al., 2019).

Trichomonas tenax and periodontal diseases

Epidemiology

The parasite *T. tenax* has been associated to the dental plaque since its identification. However, the extent of its association with periodontitis is still discussed. By PCR, the prevalence of trichomonads in periodontal pockets is 38.6% (95%-CI: 27.2%–50.0%), while it is 1.6% (95%-CI: 0.0%–3.3%) in healthy sulci, giving a risk ratio of 21.82 (95%-CI: 6.71–70.96) by meta-analysis

(Martin-Garcia et al., 2021). This is consistent with the results obtained in another meta-analysis pooling all diagnostic methods, including culture and microscopy, which revealed a prevalence of *T. tenax* of 27% (95%-CI: 10%–48%) during periodontitis (Eslahi et al., 2021).

The results vary consistently between the studies and may be explained by the differences in the definition of health and disease. Indeed, tooth mobility, accumulation of plaque, and clinical attachment loss were correlated to the presence of *T. tenax* (Bisson et al., 2018). This suggests that *T. tenax* may be associated to specific stages or grades of the disease, or even to other periodontal disease types. This underlines the need to better study the link between clinical parameters and the parasites that are not independent and may be of biological relevance.

Pathophysiology

Though *T. tenax* is cytotoxic to cells in culture and *T. vaginalis* is the etiologic agent of one type of vaginosis, the precise role of *T. tenax* in certain types of gum inflammation and periodontal diseases is still to be formally established. Several hypotheses have been presented and *T. tenax* may exacerbate gingivitis, as discussed elsewhere (Marty et al., 2017). By integrating recent data, we can hypothesize that *T. tenax* may be a superinfecting microorganism over an already present plaque-induced gingivitis, resulting in a rapid and direct cytotoxicity towards host cells. This parasite may be the etiologic agent of necrotizing gingivitis. However, formal evidence is missing, and this hypothesis should be studied by idoneous scientific explorations before further conclusions.

Conclusive remarks: Therapeutic management

Infection by *T. tenax* does not appear to be correlated to initial stages of periodontal diseases, but rather seems to be associated with some types of advanced and fast-evolving periodontal diseases. Microbiological diagnosis may help the identification of cases with a risk for rapid progression of damage. The link of immunodepression with necrotizing gingivitis, through neutropenia (Feller et al., 2012), highlights the interest to study the possibility of different etiologies and aggravating factors for these diseases with similar clinical presentations.

Trichomonads are anaerobic and vaginal trichomoniasis is efficiently treated with nitroimidazoles, which may be suitable for the elimination of *T. tenax* in the periodontal sulci. Interestingly, scaling and root planing consistently decrease parasite detection in diseased sites (Dubar et al., 2020). This result is consistent with the association of the parasite with dental plaque (Bisson et al., 2018) and recalls the importance of prophylactic or therapeutic strategies involving hygiene and non-surgical periodontal therapy in the prevention of periodontal diseases.

Trypanosomatids in oral mucosal lesions

The parasites

Discovery

Trypanosomatid parasites were described for the first time in 1841 (Valentin, 1841), while the name of genus “Trypanosoma” was used for the first time in 1843 (Gruby, 1843). The description of flagellated protozoans in cutaneous lesions (“Sart sore”) was made by Borovsky in 1898 (Hoare, 1938) but the name of the genus was later given by Ross (1903).

The oral mucocutaneous form of leishmaniasis was originally proposed to be either due to metastatic dissemination of parasites (“espundia”), or by local extension of cutaneous lesions on the face (“uta”) (Escomel, 1911) (Fig. 3). Though they may differ in

Fig. 3 “*Leishmania donovani*, Laveran: 1, red corpuscle; 2–6, free forms; 7–17, embedded forms; (A) contour line; (B) macronucleus; (C) micronucleus; (D) matrix.” From Ross R (1903) Further notes on Leishman’s bodies. *British Medical Journal* 2(2239): 1401.

clinical presentations and outcomes, a great number of the species of the genus *Leishmania* are now known to cause mucocutaneous leishmaniasis (MCL).

Cellular characteristics

Parasites from the genus *Leishmania* have two main hosts. The mammalian hosts support an intracellular mitotic replication of amastigote forms, which are rounded and short-flagellated (originally detected as unflagellated by microscopy, hence the name). These forms can infect phagocytic and non-phagocytic cells, in which they replicate until their release. Infected macrophages can be ingested during the blood meal of the insect host, the phlebotomine sandfly. When exiting the cells, the parasite differentiates into extracellular elongated promastigote forms, which possess a long flagellum and are endowed with motility. These forms replicate by mitosis within the digestive tract of the insect, to which they adhere before they are injected into a new mammalian host. They are actively internalized by professional phagocytes, in particular monocytes, in which they differentiate into amastigotes.

Genetic characteristics

The *Leishmania* genus is complex, with an increasing number of identified species, of which several can provoke pathologies in humans. Common classification of the species is done according to the geographic area where they are identified (Paleotropics or Old World, as compared with Neotropics or New World), to the site where they divide in the phlebotomine vector (parasites from the subgenus *Viannia* divide in the hindgut, promastigotes from the subgenus *Leishmania* develop in the midgut), or to the type of disease they yield (tegumentary or visceral presentations). MCL is generally attributed to *L. tropica* in the Old World; *L. braziliensis*, *L. panamensis*, and *L. guyanensis* in the New World. However, increasing numbers of studies report that other species can cause MCL.

Furthermore, the picture is more complex because the great genomic diversity of the *Leishmania* genus is enhanced by sexual genetic exchanges (Patino et al., 2020). Indeed, parasites can mate in the phlebotomine after meiosis-like events, and hybrids can be transmitted to mammals (Akopyants et al., 2009). Thus, the sandfly can be considered a definitive host, while the mammals are intermediate hosts.

Interestingly, in *Trypanosoma cruzi*, another parasite from the Trypanosomatidae family, genetic characteristics were not the only determinant for the clinical presentation of the disease in mammals, evidencing the role of host-related and infection-linked parameters (Santi-Rocca et al., 2017). Infection by *Leishmania* species might also be influenced by these parameters, causing the variety of presentation within the same taxonomic entity.

Leishmania spp. and oral mucosal leishmaniasis

Epidemiology

The parasite needs two host pools to spread: a mammal one—which can be human—and an insect one. Consequently, the areas in which human leishmaniasis is present are limited by the geographic distribution of its insect host, from the *Lutzomyia* genus in the New World and the *Phlebotomus* genus in the Old World. Strategies preventing contact between humans and insects can be efficient to control the transmission of the parasite. Thus, socio-economic parameters also impact the incidence of the disease. The WHO warns that more than 90% of the cases of MCL occur in Brazil, Bolivia, Ethiopia, and Peru (<https://www.who.int/es/news-room/fact-sheets/detail/leishmaniasis>).

The global burden of oral leishmaniasis is difficult to evaluate since the most frequent site for MCL is the nose and often indistinctly classified with cutaneous leishmaniasis. Furthermore, the declaration of the disease is not mandatory in all endemic countries, introducing a strong bias.

Pathophysiology

The possible and frequent evolution from long-lasting cutaneous forms of leishmaniasis and MCL has been identified long ago (Pessoa, 1941). Indeed, parasites can migrate from cutaneous lesions, probably carried by lymphoid cells or directly by blood, triggering a new lesion in the oral-nasal environment from weeks to years after the scarring of the initial ulcer (Handler et al., 2015).

The damage in MCL seems to be fueled by an excessive Th1 response, as compared to cutaneous lesions. However, inflammation is needed to control infection, as evidenced by the exacerbated parasite replication caused by the use of immunomodulators (TNF inhibitors), which can lead to death (Fromm et al., 2015). In parallel, ablation of Tregs results in exacerbation of the cutaneous disease provoked by *L. panamensis* infection, while adoptive transfer of naïve Tregs hindered the pathophysiology, with reduced cutaneous damages, parasite load, and cytokine production (IL-10, IL-13, IL-17, and IFN- γ) (reviewed in Conceicao-Silva et al., 2018).

It is noteworthy that data missing from the description of the pathophysiology of human MCL are completed by results for MCL in animal models or extrapolated from other types of lesions provoked by infection with parasites from the *Leishmania* genus. There is a lack of homogeneity in the species used for these description and caution should be taken when assuming mechanisms are conserved between hosts, parasite species, and clinical presentations.

Therapeutic management

The prevention of MCL resides mainly in the protection from primary infections, may they be visceral or cutaneous. The first strategy is to prevent contamination by avoiding contact with the parasite-transmitting insect vector (Stockdale and Newton, 2013). This can be done using insecticide-impregnated nets. Then, the canine reservoir of the parasite can be controlled.

The molecular identification of *Leishmania* parasites by PCR is the most sensitive method for MCL diagnosis (Cantanhede et al., 2021). However, more affordable techniques like immunohistochemistry can be an acceptable option in some endemic regions (Sanchez-Romero et al., 2020). Serological tests are of limited use due to the cross-reactivity of antibodies directed towards other trypanosomatids, and with the possible persistence of antibodies developed during visceral or cutaneous forms of the disease (discussed in Abadias-Granado et al., 2021).

It is noteworthy that, though several species can provoke MCL, differential diagnosis and treatment are not routinely made. The therapeutic management relies on the identification of parasites from the *Leishmania* genus, which is sufficient to justify the choice of a systemic therapy involving either liposomal amphotericin B (intravenous) or pentavalent antimonials (intravenous or intramuscular). These treatments are nephrotoxic and cardiotoxic, respectively. Other strategies can be considered, like the use of azoles, miltefosine, and pentamidine (reviewed in Abadias-Granado et al., 2021).

Introduction

Global estimates indicate there are approximately 374 million new curable sexually transmitted infections (STI) each year and, in many regions of the world, STI incidence is on the rise. STI comprise a diverse category of pathogens including viruses, bacteria, fungi, and protozoa, that spread primarily through sexual contact (Fig. 1). Specifically, there are currently more than 30 recognized bacterial, viral and parasitic pathogens that may be transmitted and acquired through sexual contact (World Health Organization [WHO], 2021a), and which manifest in a number of clinical symptoms (McGough, 2008). The most prevalent STI include human immunodeficiency virus, herpes simplex virus, human papillomavirus, and hepatitis B virus, syphilis, gonorrhea, chlamydia, and trichomoniasis. The spread and control of such STI is determined by a complex interplay of biological, behavioral and social factors which are influenced by political, economic, demographic, and cultural conditions (Garnett, 2008).

STI constitute a considerable disease burden and persist as a major source of morbidity and mortality around the world. Globally, the incidence and prevalence of STI varies significantly. Health inequity remains widespread, with some global regions and communities bearing a disproportionate burden of STI and sequelae. Ultimately, STI continue to have a significant impact on sexual and reproductive health, thus the epidemiological study and prevention of STI are critical to advancing global public health.

STI and epidemiology

Epidemiology is the study of the patterns, causes and risk factors of disease (Garnett, 2008). Epidemiological evidence is used to address and prevent health problems, such as sexually transmitted infections. STI epidemiology examines the patterns, causes, risk, and outcomes of acquisition at both the individual and population levels. The epidemiology of STI has shifted dramatically over the past century as a result of social, behavioral, political, economic, and demographic forces, as well as advances in diagnostic testing and procedures (Lowndes and Hughes, 2010; Aral and Holmes, 2008). The ultimate determinants of transmission include sexual behaviors and changes in sexual practices, social network formations, and the uptake of effective prevention messaging, all of which contribute to shifting STI epidemiology.

Fig. 1 STI comprise a diverse category of pathogens including viruses, bacteria, fungi, and protozoa, which manifest themselves in a number of clinical symptoms.

Importance of STI study

STI are among the most common and potentially devastating group of infections in the world. Historically, major investment from government and medical actors has been limited, however, in recent years there have been some new efforts directed at the health sector response to STI epidemics. Most notably, the *World Health Organization Global health sector strategy on Sexually Transmitted Infections, 2016–2021*, which aims to “contribute to a radical decline in new sexually transmitted infections and in deaths related to such infections (including still births and cervical cancer), while improving individual health, men’s and women’s sexual health, and the well-being of all people” (WHO, 2016, p. 2). Such initiatives are critical and must be paralleled by the ongoing study of STI, the importance of which cannot be understated, for reasons including:

1. Advances in biomedical knowledge and technology have led to new and improved diagnostic options. New diagnostic approaches have facilitated epidemic investigations that have identified various modes of transmission, prevention strategies, and the consequences of sexually transmitted infections and their sequelae.
2. New risk groups have been identified and the number of individuals affected by STI, including HIV, has increased. STI are unequally distributed; social and structural determinants of STI, including stigma and discrimination, put certain people and communities at greater risk for infection. Disadvantaged and marginalized persons, people who inject drugs, prisoners, sex workers, and men who have sex with men are disproportionately impacted by STI and sequelae.
3. STI affect hundreds of millions of people globally each year, presenting high rates of morbidity and mortality. STI and sequelae are tied to serious health complications including cancers, male and female infertility, and poor birth outcomes.
4. Left untreated, STI can have serious implications for reproductive, maternal and child health and well-being. Specifically, STI are the main preventable cause of infertility in women (WHO, 2011) and may lead to certain types of genital cancers. In addition, STI may be transmitted through mother-to-child transmission and cause adverse birth outcomes (e.g. stillbirths, prematurity, neonatal conjunctivitis).
5. Global health inequity remains a major issue. Access to treatment and prevention measures is limited in many areas of the world and continues to challenge practitioner, government, and nongovernment organization efforts to curb STI rates.
6. Sexual behaviors, which are inextricably tied to STI, are constantly evolving which means researchers, public health professionals, and clinicians are presented with new and shifting challenges.

Key factors affecting public health

The global burden of STI is high. According to estimates, there are more than 1 million new daily cases of curable STI in persons aged 15–49 years (this number includes chlamydia, gonorrhoea, trichomoniasis, and syphilis; it does not include HIV and other STI), making STI among the most common communicable diseases around the world. STI continue to adversely affect the health and well-being of individuals and communities (Rowley et al., 2019; WHO, 2019a), and remain epidemic in most of the world.

The complexities of STI transmission present major challenges to traditional public health interventions and control efforts (Fenton and Lowndes, 2004). Moreover, prevention programs that aim to curb transmission, exist in highly diverse, complex, and dynamic social, cultural and health-service settings. There are also major differences in the availability of resources, as well as in the range and extent of both prevention and intervention services among different global regions and populations. These differences may be influenced by a number of factors such as (but not limited to): the level of various STI and health conditions in

communities—communities that bear a significant burden of infection may experience a strain on often already limited resources; the level of preventive health services available; access to diagnostic tools; and the amount of financial resources put into STI prevention or management services. While in many countries access to clinics is readily available, in resource-limited regions and countries with developing public health systems, clinics and health care centers may be sparse or nonexistent altogether.

Populations at risk

There are significant differences in STI prevalence and incidence between populations. The incidence, prevalence, and population distribution of STI are largely determined by a complex interplay of dynamic environmental, demographic, economic, political, social, cultural and behavioral forces, as well as the response of health systems to emergent STI morbidity patterns (Aral and Holmes, 2008). The social and structural determinants of transmission often operate in tandem (Lowndes and Hughes, 2010), influencing risk and making certain global communities especially vulnerable to infection. Consequently, some persons and population group are disproportionately affected by STI.

1. **Adolescents:** Adolescents and young adults are particularly vulnerable to STI. Research suggests that there is a global, national, and local epidemic of STI among individuals aged 15–24 years (Reed and Huppert, 2011; Shannon and Klausner, 2018). In all societies, STI tend to concentrate in certain populations, with highest rates among sexually active adolescent females followed by adolescent and young adult men. This pattern is particularly pronounced in the West where effective prevention and control efforts result in concentrated STI morbidity.
2. **Women:** Studies indicate a gender disparity – women under 25 have higher rates of STI than any other population (Reed and Huppert, 2011). In addition, STI adversely affect the health of women and can have serious implications for reproductive, maternal, and newborn health (WHO, 2011). Women in resource-limited countries are disproportionately impacted and experience the adverse effects of STI most acutely.
3. **People experiencing poverty:** Poverty is well understood as a pathway to STI, with studies drawing a causal link between socioeconomic vulnerability and risk of infection. STI are unevenly distributed and disproportionately affect resource limited global regions. STI diagnosis and treatment are often unavailable, inaccessible, delayed, or inadequate (Bertozzi and Opuni, 2008).
4. **Marginalized persons and populations:** Men who have sex with men, transgender women, injection drugs users, prisoners, and sex workers, also experience a greater burden of disease, in part due to a lack of targeted testing and treatment, as well as poor access to care due to stigma and discrimination. Consequently these risk groups bear a greater burden of infection and disease. Moreover, there are often intersections among these groups, making certain persons and communities particularly vulnerable to STI acquisition and sequelae.

Trends in STI

Viral infections

Incurable STI are characterized by persistent viral infections that are often lifelong in duration (Mabey, 2010). Though viral STI are long lasting, they are characterized by lower transmission probabilities. Over time, and especially over the past two decades, viral infections have been increasing in prevalence in many regions of the world. At the same time, diagnosis, management and control of viral STI have changed as the introduction of new diagnostic technologies has increased recognition of viral infections.

The four most common viral STI are:

1. human immunodeficiency virus,
2. herpes simplex virus,
3. human papillomavirus,
4. hepatitis B virus.

Human immunodeficiency virus

The epidemiology of human immunodeficiency virus (HIV) has shifted since the beginning of the HIV epidemic nearly 40 years ago. HIV is transmitted through various means including exposure to infected blood or blood products, mother-to-child-transmission, and sexually—the predominant mode of transmission. There has been major progress in the prevention, diagnosis and treatment of HIV. A cure, however, remains elusive. As such, while the world has seen a decline in new infections and mortality, HIV persists as a considerable global public health issue. See Epidemiology of HIV in this edition.

Herpes simplex virus

Infection with herpes simplex virus (HSV) is common among all sexually active populations. Two types of herpes simplex virus (HSV) have been identified: HSV-1 and HSV-2. The majority of cases (85–90%) of recurrent HSV are caused by HSV-2 (Da Ros and Da Silva Schmitt, 2008; Centers for Disease Control and Prevention [CDC], 2021a). Genital herpes, caused by HSV-2, is chronic and lifelong with recurrent episodes of painful genital ulceration. Infections take an average of 3 weeks to resolve and then enter a latent

state from which recurrences of symptomatic lesions occur with decreasing frequency over time. These recurrences create a long infectious period that can expose subsequent sexual partners to infection. While HSV-1 is primarily an oral infection, it is suggested to be emerging as a rising cause of genital herpes in some settings (Looker et al., 2020).

Genital ulceration is generally more frequent, more severe, and longer lasting in immunocompromised individuals. A potential “epidemiological synergy” has been noted between HSV-2 and HIV, with HSV-2 linked to a threefold increase in sexual transmission and acquisition of HIV (Harfouche et al., 2021; Looker et al., 2020). Risk increases due to ulcers caused by HSV-2 infection which provide a direct physical route of entry for HIV, and HIV-prone activated T-cells and dendritic cells, resulting from the immune system’s response, are present in significant numbers at the site of HSV-2 infection.

HSV is one of the most common genital ulcerative STI in the world (Aral and Holmes, 2008; Hawkes, 2008). The WHO (2019a,b) estimates that globally nearly 500 million people are living with HSV, with prevalence of HSV-2 infection highest in Africa and followed by the Americas. Greatest HSV disease burden is experienced by populations in sub Saharan Africa, where HSV-2 incidence remains high and significantly higher than other parts of the world (Harfouche et al., 2021). Incidence of HSV-2 is greatest in women and particularly women living in the WHO African Region.

Seroepidemiological studies provide useful insight into the cumulative incidence and prevalence of HSV infection as they confirm the strong association between HSV seroprevalence and increasing age, number of partners during the previous year, higher seroprevalence in females compared with males, as well as the increasing proportion of first episodes of genital herpes being caused by HSV-1 instead of HSV-2 (Aral and Holmes, 2008). There is currently no cure for herpes, however antiviral medications may reduce the severity and frequency of symptoms. Available prevention modalities, such as condoms and antiviral therapy, do not sufficiently control infection spread; therefore the integration of prevention and control measures is needed. Consequently, the WHO and global partners have identified the development of an HSV vaccine and topical microbicides as a critical global priority.

Human papillomavirus

Human papillomaviruses (HPV) belong to the family *Papillomaviridae* and present among all sexually active groups. *Condylomata acuminata*, or genital warts, are caused by HPV and are spread through skin-to-skin contact (Ayadpoor and Hall, 2011). Genital warts are the clinical manifestation of infection with certain types of HPV (specifically types 6 and 11) (Lowndes and Hughes, 2010). There are more than 100 subtypes of HPV (Ayadpoor and Hall, 2011), with as many as 40 transmitted through genital-to-genital contact.

HPV is the most common STI in the world, with most sexually active persons acquiring HPV at some point in their lives. Roughly 1 million new cases of HPV are diagnosed each year and prevalence is between 24 and 40 million. Women bear a disproportionate burden of infection; globally, nearly 300 million women live with HPV (WHO, 2019a). HPV is responsible for a substantial global burden of cervical and other cancers (Chesson et al., 2017), and types 16 and 18 are particularly carcinogenic to humans, accounting for at least 70% of cervical cancer cases (Tota et al., 2011; WHO, 2022).

Although HPV is currently incurable, it is preventable. A first major step in prevention was seen in June 2006 when a quadrivalent HPV vaccine was licensed by the Food and Drug Administration for use in the US (Bryer, 2010). There are now 3 vaccines that have been prequalified and, as of late 2020, HPV vaccines were made available as part of routine immunization programmes in 111 countries (WHO, 2021a). The vaccines all provide protection against types 16 and 18—the serotypes most commonly associated with cervical cancers—and two also protect against types 6 and 11, which cause genital warts (WHO, 2020b). Vaccination is indicated for females aged 9–26 and received ideally before women become sexually active. The US guidelines recommend routine vaccination for females 11–12 years and “catch up” vaccination for young women 13–26 who have not been vaccinated previously (Ryan et al., 2008; Bryer, 2010).

While the WHO indicates, “HPV vaccination could prevent the deaths of millions of women over the next decade in low- and middle-income countries, where most cases of cervical cancer occur, if high (>80%) vaccination coverage of young women (ages 11–15) [is] achieved,” the vaccine remains inaccessible to many women in resource-limited settings, in large part due to the expensive cost. Implementation is therefore a key challenge, with significant obstacles to vaccine integration in national immunization programs (see *Program for Appropriate Technology in Health (PATH)*, 2011). Moreover, although the vaccine targets the serotypes that are most often associated with cervical cancer, the serotypes most often responsible for genital warts are not covered. Treatment costs associated with HPV and its related disease are exponential; in 2010, in the US alone, treatment costs were estimated to be in excess of \$4 billion per year (Bryer, 2010).

Hepatitis B virus

Hepatitis B infection is prevalent in much of the world, although overall incidence is declining. There are many routes of hepatitis B virus (HBV) transmission including, most commonly perinatal transmission to newborn infants, exposure to infected blood products, the reuse of unsterilized needles, syringes, or medical equipment, the use of contaminated needles and paraphernalia associated with injection drug use, and sexual exposure (Ayadpoor and Hall, 2011).

HBV is 50–100 times more infectious than HIV (WHO, 2012). Two billion people worldwide have acquired HBV and, in 2019, an estimated 296 million people were living chronic HBV (WHO, 2021b). Certain global regions bear a disproportionate burden of infection, with HBV endemic in several parts of the world including parts of Asia and many regions of Africa (Shepard et al., 2006).

The WHO (2021b) estimates that 116 million people in the WHO Western Pacific Region and 81 million in the WHO African Region have a chronic HBV infection. In contrast, in western Europe and North America less than 1% of the population is infected (WHO, 2012).

Most (90–95%) adults are able to fight the virus while the infection is in its early (acute) stage, however, between 5 and 10% experience a progression of the disease, at which point it becomes chronic. The likelihood of HBV becoming chronic depends on an individual's age at infection as chronic infection is likely to occur in younger populations (Workowski and Berman, 2010). Acute hepatitis presents few long-term consequences, however chronic cases may lead to cirrhosis and hepatocellular carcinoma (liver cancer); approximately 15–25% of people with chronic HBV die of liver disease. It is estimated that approximately 600 000 people die each year due to the consequences of HBV (WHO, 2012). Moreover, HBV-HIV coinfection is common. According to the WHO (2021b), roughly 1% of persons with HBV infection are also living with HIV and the global prevalence of HBV infection in persons with an HIV infection is more than 7%.

There is not a specific treatment course for acute HBV, though chronic HBV infection may be treated with antivirals. Given high HBV-HIV coinfection, as of 2015, the WHO has recommended treatment for anyone diagnosed with HIV infection, regardless of disease stage.

HBV transmission can be prevented through the use of condoms and education of the disease, particularly to partners regarding the potential of transmission through body fluids (Ayadpoor and Hall, 2011). There is also a safe and effective vaccine that provides 98–100% protection, with protection lasting at least 20 years. The HBV vaccines series is recommended as part of routine vaccination and the WHO recommends that all infants are vaccinated as soon as possible after birth. However, adoption of this has been slow and is limited in resource-poor countries.

Bacterial infections

Most treatable STI are caused by bacteria and protozoa (Mabey, 2010). This group of STI is characterized by a relatively short lifespan and a high probability of transmission (Garnett, 2008). The prevalence data and the estimated duration of infection suggest that there were more than 376 million new cases of bacterial STI in individuals 15–49 years of age worldwide in 2016 (Rowley et al., 2019). The introduction of new diagnostic technologies has improved sensitivity in identification of bacterial STI. The use of urine and vaginal swabs has expanded the coverage of screening services and has led to the availability of true population-based estimates of the prevalence of STI (Aral and Holmes, 2008).

Despite a period of decline in some parts of the world, more recently the incidence of bacterial STI has increased significantly. Rates of some bacterial STI remain high or have seen an uptick in certain subpopulations (e.g., gay, bisexual or other men who have sex with men; Grant et al., 2020); reinfections and co-infections are also common (Rowley et al., 2019). An individual is susceptible to infection or reinfection due to a lack of acquired immunity.

The major bacterial STI include:

1. syphilis,
2. gonorrhea,
3. chlamydia.

Syphilis

Treponema pallidum, the spirochete that causes venereal syphilis, has a highly variable clinical course (Ayadpoor and Hall, 2011). It is a genital ulcerative disease that may cause significant complications if left untreated (Da Ros and Da Silva Schmitt, 2008). It is spread through direct contact with a syphilitic lesion or rash during vaginal, anal, or oral sex as the bacteria can enter the body through the penis, anus, vagina, mouth, or through broken skin. A pregnant woman living with syphilis can also pass the disease to her infant through vertical transmission in utero or during birth. Like other bacterial STI, syphilis facilitates the transmission of HIV.

While prevalence has declined in some regions, syphilis continues to cause morbidity and mortality around the globe. Estimates suggest that, annually worldwide, there are approximately 6 million new cases of syphilis in persons 15–49 years of age (Kojima and Klausner, 2018). Despite efforts to reduce syphilis incidence, some high-income countries (e.g., regions in Western Europe, the United States, United Kingdom and Canada) have recently seen concerning rise in rates of infection and outbreaks in specific populations. However, low- and middle-income countries continue to bear the greatest burden of disease, where rates of syphilis infection remain at endemic levels among general populations (Kojima and Klausner, 2018).

Outbreaks of syphilis disproportionately impact specific populations globally, including men who have sex with men, transgender women, sex workers, in part due to a lack of targeted testing and treatment, as well as poor access to care due to stigma and discrimination (Kojima and Klausner, 2018). Untreated syphilis has a number of severe health outcomes, including increasing risk of HIV infection through direct skin-to-skin contact with syphilis sores. Pregnant women and newborn children also bear a disproportionate burden of adverse health outcomes; untreated infection in pregnancy can result in mother-to-child transmission and accounts for approximately 200,000 preventable stillbirths and newborn deaths each year (Lawn et al., 2016).

Rapid, point-of-care testing for syphilis are available; rapid testing can be done without electricity or laboratory equipment and can be performed on blood samples obtained by a single finger-stick (Mabey, 2010). The management of syphilis outbreaks focuses on active partner notification, enhanced surveillance of infectious syphilis and the investigation of sexual networks facilitating disease transmission. Interventions center on enhancing both public and health care worker awareness, venue-based screening, rapid testing within- and outside treatment centers, targeted sexual health promotion and syphilis screening of HIV positive individuals. Single-dose benzathine penicillin given intramuscularly remains the mainstay of treatment for primary syphilis and is a highly important medication for resource-limited settings.

Gonorrhea

Gonorrhea, caused by *Neisseria gonorrhoeae* bacterium infection, grows easily in the reproductive tract including the cervix, uterus, and fallopian tubes in women and in the urethra in women and men. Gonorrhea can also grow in the mouth, throat, eyes, and anus. There is little evidence suggesting protective immunity and, more recently, antimicrobial resistance to antibiotics has increased rapidly (WHO, 2019a,b). Consequently, a person can be infected with gonorrhea multiple times throughout their lifespan. There is significant concern about the threat of increasing global incidence of drug-resistant gonorrhea (e.g., Eisinger et al., 2020), as it ultimately presents a challenge to public health efforts aimed at reducing STI impact on a global scale (WHO, 2019a,b).

Gonorrhea is the second most commonly reported notifiable STI and recent global incidence is estimated at more than 82 million infections annually among adolescents and adults aged 15–49 years (WHO, 2021b). Women under 25 years of age are at highest risk of infection. The relatively large increase in the number of cases in young women since the mid-1990s suggest that heterosexually acquired infections have increased significantly, yet, infections acquired through sex between men continue to account for a disproportionate number of infections. An increase in gonorrhea among men who have sex with men and bisexual men has also been reported in some world regions, such as the US.

Education on transmission and prevention, condom use, partner notification, STI screening, and limiting the number of sexual partners are key prevention strategies. However, the emergence of antimicrobial resistant gonorrhea has created additional obstacles to the control of infection. In many parts of the world, quinolone antibiotics are no longer effective and more expensive cephalosporin antibiotics are required to successfully treat infections. The development of a vaccine against the infection is also essential. The combination of persistently high gonorrhea morbidity in some populations and the threat of drug-resistant gonorrhea reinforce the need to better understand the epidemiology of the disease.

Chlamydia

Chlamydia is a common STD caused by *Chlamydia trachomatis* (*C. trachomatis*). While infection is generally asymptomatic (symptoms are usually mild or absent altogether), chlamydial morbidity can lead to serious health complications and irreversible damage. Chlamydial infections appear to be rising—in 2005, there were 101 million cases of chlamydial infection worldwide (Mabey, 2010), just over ten years later, in 2016, the WHO reported an estimated 127 million cases (WHO, 2019b). It is the most commonly reported bacterial STI in high income countries; for example, in 2016, the U.S. had nearly 1.6 million known cases of chlamydia (CDC, n.d.).

More cases of STI are caused by *C. trachomatis* than by any other bacterial pathogen, making such infections an enormous public health problem throughout the world. Infection is persistent in groups with good access to treatment due to a typically longer disease course (Mabey, 2010). Women bear a disproportionate burden of chlamydial incidence and it is most common among women aged 15–24 years. Women in resource-poor countries experience the impact of infection most acutely, as the serious health risks and adverse outcomes associated with chlamydia are magnified.

There has been an increase in global diagnoses of chlamydia due to changes in sexual behaviors (specifically among youths) and improvements in diagnostic testing. Cure rates are currently 97–98% (Ayadpoor and Hall, 2011), with appropriate antimicrobial therapy. Untreated infection, however, can lead to serious health complications including infertility, pelvic inflammatory disease (PID) and neonatal complications.

The range of chlamydia control strategies and activities is broad. In high income settings, there tends to be a focus on screening for asymptomatic cases. For instance, the US CDC recommends chlamydia screening for all sexually active women under 26 years of age (Da Ros and Da Silva Schmitt, 2008). Where screening has been introduced, the prevalence of infection and rates of PID are decreasing. It has been suggested that the screening of sexually active young men should also be considered in clinical settings with a high prevalence of chlamydia, such as adolescent clinics and detention facilities (e.g., prisons and jails) (Da Ros and Da Silva Schmitt, 2008), though the WHO *Global health sector strategy on STI, 2016–2021* reports that “best strategies to control and measure chlamydia infections are still to be defined” (p. 17).

The treatment of chlamydia consists of single-dose Azithromycin, or when not available, a 7 day course of Doxycycline. Treatment should also be given as presumptive therapy for individuals presenting with confirmed or presumptive gonorrhea.

General care and management of STI

Reporting

The underreporting of STI that are deemed to be “reportable” to public health departments is of concern. Few countries outside Western Europe and North America have accurate reporting systems for STI, thus, in most of the world, the true incidence of STI is

generally unknown (Mabey, 2010). The UK has a unique network of treatment centers that are dedicated entirely to the management of STI (genitourinary medicine or GUM clinics), from which statistical reporting constitute the basis of national STI surveillance programs (Fenton and Lowndes, 2004). In the US, it is estimated that reported cases of STI represent only 50–80% of reportable STD, reflecting both limited screening and low-disease reporting. By contrast, many EU states rely on a combination of sentinel reporting, mandatory disease notification or laboratory reporting to monitor trends (Fenton and Lowndes, 2004). Epidemiological knowledge is based on the results of ad hoc prevalence surveys of convenience populations, of concern such data may be unrepresentative of the wider population (Mabey, 2010). Over time, the epidemiology of STI in sub-Saharan Africa has been improved through the introduction of large population-based prevalence surveys (Mabey, 2010). The results of these surveys have confirmed the high prevalence of STI such as syphilis in the region.

STI diagnosis

Adequate screening for STI should be done on a routine basis in every part of the world. Many STI are asymptomatic and thus can be difficult to control. The purpose of screening is to ensure that persons who experience infection will be quickly diagnosed and appropriately treated to avoid serious health consequences and reduce the spread of STI.

Diagnostic testing

Since the 1990s, a number of new initiatives have promoted diagnostic test development for STI control. Over the years, progress in science and technology and funding from major international donors have led to the development of “rapid” STI tests (Ryan et al., 2008). The introduction of new diagnostic technologies has greatly increased the recognition of viral STI, enhanced the sensitivity of detecting bacterial STI, and expanded the repertoire of usable specimens (Aral and Holmes, 2008). New, simple, rapid, cheap point-of-care serological tests for syphilis, for example, which can be performed on whole blood obtained from a fingerprick are now available and hold much potential for improving STI control. The use of vaginal swabs and urine has also significantly expanded the screening service coverage and has led to the availability of true population-based estimates of the prevalence of STI (Aral and Holmes, 2008). The STI Diagnostics Initiative located in the UNICEF/UN Development Program/WB/WHO Special Programme for Research and Training in Tropical Disease is one of the most notable of diagnostic initiatives (Ryan et al., 2008). The *WHO Global health sector strategy on STI, 2016–2021*, also reflects a growing recognition of the importance of integrating rapid point-of-care tests into STI control strategies. Diagnostic testing is crucial as, in diagnosing and treating patients with STI, effective prevention efforts may be advanced and consequently reduce the spread of STI around the world. However, diagnostic testing is not readily available to all global regions.

Syndromic diagnosis

The biggest challenge in STI management is ensuring that adequate-quality, rapid tests are accessible to resource-limited settings that need them most. Laboratory tests provide the most specific evidence of infections, however, such tests are not readily available at all clinical sites (Ryan et al., 2008), as they are often unavailable or simply too expensive (even when available, test results may not be available soon enough to guide appropriate treatment) (WHO, 2011). As such, low- and middle- income countries are especially dependent on “syndromic management.” The basis of this approach is the identification of a syndrome through consistent and easily recognizable signs and symptoms associated with a limited number of well-defined etiologies (Ryan et al., 2008; WHO, 2019a,b). This approach uses clinical algorithms and flowcharts to guide diagnosis and treatment (WHO, 2011, 2019b). In essence, treatment are determined by the likely etiology, as opposed to etiologic diagnosis.

Syndromic management is relatively simple and cost effective, thereby making it a more feasible option for regions that lack adequate laboratory infrastructure. However, syndromic diagnosis also has several limitations. This approach cannot detect asymptomatic infections, can lead to overdiagnosis and an overuse of treatment (due to the conflation of symptoms with those of another condition), and drug resistance. Moreover, a syndrome-based approach may impede accurate surveillance data. As an example, while syndromic management of genital ulcers and genital discharge in men has been shown to be relatively straightforward and cost effective, the same cannot be said of syndromic management of genital ulcers and genital discharge in women as symptoms are poor predictors of the presence of an STI. Inexpensive, simple, dipstick-type tests (i.e., point-of-care tests) for gonorrhea and chlamydia infection would significantly aid in diagnosis, but the availability of such testing remains limited.

Behavioral prevention

STI prevention programs have relied heavily on biomedical models, however, behavioral interventions must continue to be at the center of STI prevention and control efforts. Behavioral interventions aim to curb STI transmission by changing risk behaviors to safer sex strategies. Interventions target various behaviors and attempt to modify individual behaviors, partner behaviors, and community behaviors. Interventions target social norms and influence social networking, resources and opportunities. Some such interventions include educational programs, treatment programs or face-to-face counseling programs for high risk populations.

Behavioral approaches may have the capacity to more broadly prevent STI (as opposed to more singular STI prevention typical of biomedical interventions). By incorporating the risk behaviors of a particular population or subpopulation and considering local

(i.e., contextual) factors, more appropriate interventions may be created. Moreover, the implementation of integrated behavioral prevention interventions may result in decreased transmission of STI. However, behavioral change is complex (WHO, 2021a). Some researchers have pointed to a “limited public health impact of behavioral interventions” (Aral, 2011, p. ii32) as the efficacy of this approach rests on the knowledge, attitudes and beliefs of individuals, nevertheless counseling and education have been shown to be particularly useful or effective in some settings.

Contact tracing

Contact tracing, or “partner notification,” is an essential prevention strategy used by public health practitioners to help limit the spread of STI. When an individual is diagnosed with a traceable STI, any individual with whom they have been in sexual contact must be notified. In some settings, upon diagnosis an individual is required to contact sexual partners directly; in others, public health officials attempt past partner notification of potential exposure. Although contact tracing is widely promoted, the contribution of this intervention in reducing the transmission of STI continues to be debated. There are obvious limitations to this approach including having accurate information about the potential contacts, finding the contacts when identified, and creating risky situations for the individuals providing the information to public health officials.

Treatment challenges

Despite many decades of modern public health interventions, new biomedical tools, good antimicrobial options, and a comprehensive understanding of STI transmission, the severe health and social consequences of STI persist. Human sexual behaviors create a level of complexity that has challenged public health policy and practice. In addition, issues related to resource access, service delivery, technology dissemination, and acceptability of the interventions pose considerable challenges. The development of effective vaccines and better drugs should continue to be a priority while available STI prevention tools are scaled up. Moreover, ensuring these are available and accessible to persons and communities across all global regions remains imperative.

Conclusion

Opportunities for sexual health gain and the control of STI

In recent years there have been renewed efforts to combat STI. In 2016, the WHO released the *Global health sector strategy on Sexual transmitted infections, 2016-2021* to “accelerate and focus comprehensive prevention efforts through scaling up evidence-based combined behavioural, biomedical and structural approaches; facilitate people’s access to information on their sexually transmitted infection status; improve access to treatment and comprehensive long-term care when needed; and challenge pervasive stigmatization and discrimination” (p. 2). Some nations have also indicated a political commitment to sexual health (for instance the Government of Canada 2019 Action Plan *Accelerating Our Response—Government of Canada Five-Year Action Plan on Sexually Transmitted and Blood-Borne Infections*; Public Health Agency of Canada (PHAC), 2019). However there continues to be a pressing need for government commitment, strategic leadership and action globally and across nations.

Public health intervention is also critical to sexual health gain and control of STI. “Care management” provides a useful way forward for both prevention and management of STI and includes the management of both asymptomatic and symptomatic individuals (Ryan et al., 2008). The major steps in effective care management include:

- risk assessment and clinical evaluation;
- identification of individuals with STD who are unlikely to seek diagnostic and treatment services;
- appropriate diagnosis and treatment of infected persons;
- strategies to avoid new infection and reinfections, such as prevention education, counseling, and partner notification;
- effective evaluation, treatment and counseling of sex partners of STI-infected persons;
- pre-exposure vaccination of at-risk persons of vaccine-preventable STI (Ryan et al., 2008).

Given the evolving epidemiology of STI, it is clear that substantial health gains can be obtained from such an approach. Further, greater investment in efficient and effective treatment, diagnosis, prevention, and surveillance is also urgently required. Recent reviews of effectiveness of prevention should be used to not only guide, but prioritize investment in STI (Lowndes and Hughes, 2010). Stigma and discrimination also pose key obstacles for effective STI prevention, care and treatment; efforts to address stigma and discrimination, including racism, sexism, and gender-based violence, are urgently needed (Jackson and Tremblay, 2019).

Moreover, there is a need for prolonged investment in STI prevention, microbiology, and surveillance research (Fenton and Lowndes, 2004). Public health gains are also likely to be achieved through interdisciplinary and multi-sectoral research and collaborations that focus on key areas and issues of concern. Given sufficient resources and commitment, it is possible to control STI and sequelae through provision of accessible, acceptable, and affordable clinical services, combined with partner notification and screening programs in high risk groups. Control of STI could significantly reduce the incidence of sexually transmitted infections worldwide and have a major impact on the overall health and well-being of hundreds of millions of people each year.

Introduction

Skin and soft tissue infections (SSTIs) have a pivotal role among bacterial infections, as they cause about 10% of hospital admission in developed countries, as epidemiologic investigations in the United States report (Esposito and Noviello, 2016). Many factors contribute to the increase of SSTIs in terms of frequency and severity, including the aging of the general population, the growing number of critically ill or immunocompromised patients, and the emergence of multidrug-resistant (MDR) pathogens. A study comparing cases of SSTI observed in the US in the year 2000 and in the year 2012 highlighted an increase of the total number of ambulatory and Emergency Department visits for SSTI >30%, which was mainly associated with a higher burden of SSTI in older adults. This increase of SSTI incidence was evident in all health-care settings and reported a considerable increase in terms of the costs associated to the disease (Tun et al., 2018).

SSTIs presentation can range from mild to severe life-threatening manifestations, which can affect all age groups regardless they are immunocompromised or having chronic diseases. Underlying conditions can affect SSTI severity and prognosis and several factors can influence their etiology, and clinical presentation. Immunologic status, previous antimicrobial treatments, geographic localization, recent history of trauma or surgery, animal exposure, and bites should be considered in establishing the diagnostic and therapeutic strategies for a patient reporting an SSTI (Sartelli et al., 2018a).

All these considerations on SSTI suggest that every case needs an accurate evaluation and clinical observation to avoid both the severe, life-threatening complications of under-treatment and the problems related to over-diagnosis of SSTIs as those occurring in patients suffering stasis dermatitis or honeybee stings with venom reactions. A large multicenter trial of patients presenting to an emergency department, demonstrated that a presumptive diagnosis of cellulitis, which is the most common skin infection, accounting for 650,000 hospitalizations in the United States annually, was not confirmed in 30% of the patients after dermatological consultation. In this study, venous stasis dermatitis, erythema migrans, contact dermatitis, eczema, and erythema nodosum were the most common mimics of cellulitis (Raff and Kroshinsky, 2016).

Blood and skin cultures from patients with SSTI have low yields, making the etiologic investigations of relatively low value outside selected population reporting extensive and chronic infected lesions. As a general concept, microbiologic investigations of SSTIs are positive in 30% of the cases only and *Staphylococcus aureus* and β -hemolytic streptococci (BHS) are the commonest etiologic agents. The majority of SSTIs reports a monomicrobial etiology, and a polymicrobial etiology can be demonstrated in about 20% of the cases (Esposito et al., 2019a).

SSTI: Classifications and definitions

Intact skin is a physical barrier, which provides an effective protection from the external injuries and maintains a microbiologic environment that makes difficult the growth of pathogenic organisms. SSTIs can occur after microorganisms invade otherwise

healthy skin. In some cases, an underlying disease or trauma favors the infection due to the loss of physiological barrier function. The damage is due to the destruction of affected tissues that causes an inflammatory response, which is clinically characterized by pain, local warmth, and erythema. In particular settings, such as in patients living with diabetes mellitus or neuropathies, the degree of skin damage can be high and healing of lesions can be delayed, making SSTI management more complicated. In these settings, recurrent episodes or the evidence of non-healing lesions warrant further investigations to assess vascular and lymphatic compromise, suggesting the need for a multidisciplinary approach (Labreche et al., 2013).

SSTIs represent a heterogeneous array of disorders, and several classifications have been proposed. Every attempt of classification organizes SSTIs based on the characteristics of a specific variable, such as anatomic localization, causative agent, extension of the skin lesion, progression rate, clinical presentation, and severity. Each of these classifications has its own usefulness, but some of them have poor value in driving toward the most appropriate management of the condition. In the attempt to satisfy the need of a practical, useful, and accurate evaluation, the Infectious Diseases Society of America (IDSA) classification adopts three different distinctions: (i) skin extension: uncomplicated typically superficial infections (uSSTIs) and complicated infections (cSSTIs), usually with deep involvement; (ii) rate of progression: acute and chronic wound infections; and (iii) tissue necrosis: necrotizing and non-necrotizing infections. However, IDSA classification does not fulfill the need to standardize the evaluations to be adopted to SSTI patients involved in pivotal trials evaluating the efficacy of antibiotic treatments. For this purpose, the US Food and Drug Administration (FDA) introduced a new definition of acute bacterial skin and skin-structure infection (ABSSSI) that includes cellulitis/erysipelas, wound infections, and major cutaneous abscesses. Thus, an ABSSSI is currently defined as a bacterial infection of the skin with a lesion size area of ≥ 75 cm² (lesion size measured by the area of redness, edema, or induration) (Esposito et al., 2017a).

Table 1 provides a practical classification of SSTIs based on the severity of local and systemic findings.

Microbiologic characteristics of SSTI

Microbiologic characteristics of SSTI are strongly influenced by the site of infection. For example, a study evaluating patients with facial infections reported group A β -hemolytic streptococci (GABHS) in about 75% of the cases and highlighted staphylococci as the second most frequent causative agent (Rath et al., 2018). Instead, if we look at lower extremity infections, these are more frequently caused by non-GABHS such as *Streptococcus agalactiae*. *S. aureus* and BHS are the main etiologic agents of uncomplicated SSTIs; BHS is the primary cause of erysipelas (Jones et al., 2003).

Staphylococci and streptococci sustain most cases with skin abscesses, and the bacteria that constitute the normal skin flora boost their virulence. When we look at the patients affected by cellulitis, we find that GABHS or *S. aureus* are frequently involved. *S. aureus* is considered the most common pathogen, with an increasing prevalence of MRSA strains in emergency department and ambulatory outpatient visits. Considering the data deriving from the analysis of particular groups of patients, those with chronic venous stasis or with saphenous vein harvest for coronary artery bypass surgery, showing a significant body weight and reporting a surgical procedure during 30 days prior to medical consultation, can have a Gram positive microorganism cultured from the site of infection. *S. aureus* is frequently isolated during the immediate post-operative period and BHS is cultured during the following period. Similarly, recurrent episodes of cellulitis in patients with lymphedema are frequently sustained by BHS. Staphylococci and BHS are also the most common pathogens in bacterial infections among drug users, which can be complicated by hematogenous dissemination. Gram negative and anaerobic bacteria are more common in association with surgical site infections (SSIs) of the abdominal wall or with infections of the soft tissue in the anal and perineal region, due to the specific characteristic of the bacterial flora in these parts of the body (Esposito et al., 2019b).

SSIs and SSTIs can have particular epidemiologic aspects in those with cytotoxic therapy-induced granulocytopenia. In these cases, extended-spectrum β -lactamase (ESBL)-producing Enterobacteriaceae and carbapenem-resistant *Pseudomonas aeruginosa* constitute about 10% of the etiologic agents reported (Jääskeläinen et al., 2017). Other settings that deserve particular attention include patients with hematologic malignancies or living with a transplanted organ. In these cases, we can observe an *Ecthyma gangrenosum*, which is caused by the cutaneous hematologic seeding of hospital-acquired microorganisms such as *P. aeruginosa*, *Stenotrophomonas maltophilia*, and other bacteria and fungi otherwise infrequently involved in SSTIs. Patients reporting neutrophil defects, cellular immunodeficiency including HIV, transplant, immunosuppressive medications, and diabetes can develop cellulitis due to unusual organisms, such as Gram negative bacilli, anaerobes, and other opportunistic pathogens such as *Mycobacteria* and

Table 1 SSTI classification according to the severity of local and systemic signs.

Class	Patient criteria	Site of care
1	Afebrile and healthy, other than cellulitis	Send home on oral therapy
2	Febrile and ill appearing, but no unstable comorbidities	OPAT with possibility to switch to oral therapy
3	Toxic appearance, or at least on unstable comorbidity, or limb-threatening infection	OPAT with possibility of hospital admission
4	Sepsis syndrome or life-threatening infection (e.g., necrotizing fasciitis)	Hospital admission

OPAT, Outpatient parenteral antibiotic therapy; SSTI, skin and soft tissue infection.

fungi. Subcutaneous injection of illegal drugs can cause cellulitis from uncommon bacterial species, such as *Enterobacteriaceae*, *Enterococcus faecalis*, *Bacteroides* spp., and *Clostridium* spp. Other uncommon causes of cellulitis are *Neisseria meningitidis*, *Mycobacterium avium*, *Pasteurella multocida* (which is associated with animal bites), *Aeromonas hydrophila* (after contact with freshwater), *Chromobacterium violaceum*, and *Vibrio vulnificus* (after contact with seawater) (Barbier and Timsit, 2000).

When we analyze the spectrum of hospital-acquired bacteria, focusing on patients requiring intensive care, we find that *Acinetobacter baumannii* is the main emerging MDR pathogen causing soft tissue infections, including cellulitis, after the use of invasive devices. Current data indicate that methicillin-resistant *S. aureus*, *A. baumannii* and *Pseudomonas aeruginosa* can be important pathogen in patients with burn wounds, due to their relevant profile of resistance, which makes the treatment difficult and favors an increase in terms of sepsis related mortality (Joy et al., 2020).

Necrotizing fasciitis is frequently sustained by *S. aureus* and GABHS, alone or in combination, in selected areas also *Vibrio vulnificus* can be identified and reports the highest mortality rate (Tsai et al., 2021).

Moreover, Gram positive cocci, especially *S. aureus*, are the main pathogens causing diabetic foot infections, but Gram-negative pathogens can be reported in those with chronic infection receiving multiple antibiotic treatments. Infections in patients suffering foot ischemia or gangrene can be caused by obligate anaerobic pathogens (Watkins and David, 2021).

Polymicrobial infections account for about 10% of cases of SSTI, and both Gram-positive and Gram-negative organisms can be the causative agent. According to general considerations, polymicrobial infections provide a complex environment in which a variety of interactions occurs between local flora and causal pathogens, which finally share virulence determinants and trigger the synergistic release of cytokines, boosting the severity of the infection. Most of the polymicrobial SSTIs can be included in the following: diabetes-related foot infections (DFIs), pressure ulcer infections, and burn infections (Esposito et al., 2019a).

Microbiologic diagnosis

Patients with SSTI receive different diagnostic workup with respect to underlying condition and infection severity (Esposito et al., 2011).

Blood cultures should be considered as part of the diagnostic work-up in all cases with severe infection requiring hospitalization, but they have a very low yield in patients affected with an uncomplicated SSTI. A study on 132 patients admitted because of an SSTI highlighted that only a minority of cases (10.6%), satisfied IDSA SSTI criteria for obtaining blood cultures: six animal bites, five patients with severe cellular immune deficiency and three immersion injuries in non-sterile water, but blood cultures were attempted in about 50% of the cases with positive results in 6% only. Moreover, only 2 patients had a positive culture that was consistent with the clinical findings, instead in 2 cases the bacteria retrieved were contaminant (Sturkie et al., 2021).

Although swabs from infected sites are the samples cultured with the highest frequency among patients with SSTI, it is important to emphasize that superficial swabs of open ulcers and drainage from fistulous material usually do not correctly identify the microbiologic etiology. Cultures and microscopic examination of cutaneous aspirates, pus, biopsies should be considered in complex infection, septic and immunosuppressed patients, water- or soil-related injuries, and animal bites. In patients with deep tissue infections, the results of superficial techniques do not reflect the etiologic pathogen because of the presence of commensal microorganisms on the wound surface, which explains the low specificity of the diagnostic investigation. Quantitative cultures can be proposed to distinguish commensal microbiota from clinically significant bacterial growth, but the usefulness of this technique has been questioned by prospective studies (Esposito et al., 2017b).

Yields of cultures attempted from materials obtained after needle aspirations of the inflamed skin are positive in an extremely variable number of cases (<5–40%, on the basis of the different studies) (Esposito et al., 2016a). Cultures of punch biopsy specimens yield an organism in 20–30% of cases. If an abscess is present, puncture and aspiration of fluid should be performed. SSTIs without any evidence of liquid collection should be investigated by a small biopsy of skin or soft tissue, after superficial disinfection and excision of necrotic tissue. Chronic wounds can be investigated by pus or fluid culture; alternative samples to biopsy include aspiration of saline that has just been infused into the wound depth (Esposito et al., 2016a).

Molecular technologies can be considered an effective, time-saving alternative to overcome the delay in the results associated with traditional bacterial culture. Polymerase chain reaction (PCR)-based techniques are equally sensitive as cultures, but they can be useful for the diagnosis of SSTIs sustained by *S. aureus*, potentially providing crucial information to the choice of appropriate antibiotic regimen, such as the rapid detection of Panton-Valentine leucocidin-encoding genes from pus samples or to the identification of cryptic resistances. A recent study investigating the impact of a SSTI management based on a Gram stain plus a specific PCR assay highlighted that such approach resulted in several advantages including a reduction of the treatment period, relative costs, incidence *Clostridium difficile* colitis, and finally mortality (Bouza et al., 2020; Saeed et al., 2018).

Imaging studies

Imaging studies ameliorate the accuracy of SSTI diagnosis. Plain radiography has a relevant role in detecting the presence of gas in the soft tissues, which is suggestive of a necrotizing infection, or in diagnosing an osteomyelitis. However, an X-ray examination has poor value in patients with cellulitis, unless a history of trauma or chronic wound are present, as assessed by a study investigating over 150 patients (Stranix et al., 2015). Computed tomography (CT) scans can give useful information on the extent of the

infectious process and can be crucial in guiding fluid aspiration and in revealing the presence of foreign objects or even small fluid–air collections in the soft tissues (Mower et al., 2019).

Magnetic resonance imaging (MRI) has the advantage of a better definition of soft tissues and can be particularly helpful in differentiating cellulitis from pus and abscess formation. Moreover, MRI provides better accuracy than CT in detecting necrosis, inflammatory edema, and muscular fascia involvement, but its use is limited because of cost. Moreover, the value of MRI can be high in diagnosing patients with severe cellulitis and osteomyelitis, distinguishing cellulitis, phlegmon, adjacent soft tissue ulcers, and cortical bone destruction (Klein et al., 2020).

Ultrasonography (US) can be a sensitive technique for SSTI diagnosis, reporting important advantages over other imaging studies, including MRI due to it is easy to perform, cost-effective, and can be used in guiding infected purulent secretion drainage (Alsaawi et al., 2017). In fact, ultrasonography provides useful information to differentiate cellulitis from abscess, therefore limiting more expensive imaging studies and unnecessary harmful procedures like incision and drainage. Moreover, ultrasonography is an easy and rapid technique without side effects that can be performed in many cases where MRI cannot be performed. A study on 62 patients in a rural tertiary care academic medical setting highlighted that an US examination as part of the preliminary assessment of patients with SSTI changed the diagnostic decision in 16% of the cases, increasing the number of patients treated by drainage or needle aspiration. A systematic review identified 5 studies investigating the value of US examination. Sensitivity of US examination ranged between 75 and 90%, and specificity between 55 and 83%. Use of US examination as diagnostic tool led to appropriate changes in the therapeutic approach in 16 to 39% of patients (Knaysi et al., 2021).

Radionuclide scanning studies generally lack specificity in the acute situation, but the use of hybrid techniques (such as single-photon emission tomography [SPECT]/CT and positron emission tomography [PET]/MRI) can increase the specificity of nuclear medicine imaging techniques, eventually revealing the compromise of surrounding structures. The role of these techniques in supporting SSTI diagnosis needs further investigations (Esposito et al., 2017a).

Indications for hospital admission

SSTIs are among the most common reasons for hospitalization of adults in the United States. Hospitalization costs of SSTIs can range from \$6000 to \$13,000 per patient (average cost of \$8000 per patient), with multi-day room and board expenses comprising 50% of total costs (Lodise et al., 2015).

Several authors have attempted to identify the items to be considered for assessing the need for hospital admission of patients with SSTI and several aspects have to be evaluated to establish the circumstances that warrant hospital admission for patients with SSTI. Medical history of previously untreated or relapsing skin lesions, presence of fever or relevant co-morbidities (e.g., vascular insufficiency, neuropathy, diabetes, and immunosuppression), the site of the lesion itself (the hand or head has the potential for more significant damage), aspects of laboratory investigations (e.g., elevated white blood cell count and lactate levels), and the degree of the body surface (>9%) involvement must be considered to recommend hospital admission (Estrada et al., 2020). A multicenter, prospective study on adult patients with SSTI seeking Emergency Department cares with symptoms onset within 7 days highlighted that about 15% of the cases were hospitalized with the highest frequency among those needing parenteral antibiotics for SSTI treatment (about 40% with SSTI as the only reason for admission), those requiring surgery and those reporting an underlying disease (Talan et al., 2015). Overall, most patients with uncomplicated SSTIs can be managed as outpatients. Complicated infections often require hospital admission, especially if muscle or fascial involvement is suspected, the process is rapidly progressing toward relevant lesions or septic shock, signs of toxemia are developing, the diagnosis or prognosis is in doubt, exploratory surgery is contemplated, or the patient cannot adequately comply with outpatient treatment.

Treatment of SSTI

The following aspects have to be considered in establishing the treatment of an SSTIs

- Anatomic localization
- Etiologic agent
- Skin extension (localized or widespread infection)
- Rate of progression (acute or chronic disease)
- Clinical presentation (primary or secondary infection)
- Severity (presence of co-morbidities)

In general, superficial infections are not complicated or severe, and an oral antibiotic treatment or even topical treatment can be sufficient for the resolution. The extension of the lesion on the skin, the rate of progression, and finally the necrotizing or non-necrotizing characteristics of the infection are the main aspects to be considered in treating deep infection. All these considerations are extremely important for the choice of the antibiotic regimen, particularly when necrotizing lesions are present (Sartelli et al., 2018b).

As a general concept, SSTIs can need hospitalization for the treatment of complication and sometimes of the septic status. Several authors have attempted to identify predictors for admission, as their correct evaluation would play a central role in choosing appropriately the best site of care. One of the best attempts comes from Eron et al. (2003), who took into consideration the general clinical conditions of the patient affected by an SSTI, considering four different classes, with each class corresponding to different needs regarding the site of care (Tables 2 and 3). This kind of predictor can drive clinical choice, identifying the patients that need an outpatient parenteral antibiotic therapy (OPAT) approach instead of hospitalization (Eron et al., 2003; Palit et al., 2021).

OPAT is a treatment model widely utilized in the United States and several European countries and refers to antibiotic administration given in settings other than a traditional hospital stay, including the patient's home, the general practitioner's office, the hospital ambulatory unit, and public or private infusion centers. This treatment model reports the relevant advantage of reducing hospitalization, giving the same therapeutic opportunities. SSTIs are a common indication for OPAT treatment. Several controlled trials comparing patients receiving intravenous antibiotic treatment of cellulitis at home with those receiving hospital treatment not only showed no difference in outcome and greater patient satisfaction with home treatment, but also significant cost savings accrued from real or potential reductions in hospital stay. Antibiotics used for OPAT treatment of SSTI must be effective

Table 2 Treatment of non-necrotizing infections.

Diagnosis	Etiology	Antibiotic Choice	Note
Impetigo	<i>Staphylococcus aureus</i> , BHS	Local mupirocin or chlortetracycline	In case of suspected or proven MRSA: doxycycline, clindamycin
Furuncles and Carbuncles	<i>Staphylococcus aureus</i>	As impetigo	As impetigo
Animal bites	Gram-negative (<i>Capnocytophaga Canimorsus</i> and <i>Pasteurella multocida</i>)	Oral amoxicillin ampicillin/sulbactam	In case of severe wounds: parenteral piperacillin/tazobactam or carbapenems
Cutaneous ^a abscesses	<i>Staphylococcus aureus</i>	Incision and drainage Amoxicillin/clavulanate	In case of suspected and proven MRSA: TMP-SMX clindamycin, Tetracyclines, linezolid, fusidic acid As alternatives: first- and second-generation cephalosporins
Erysipelas ^a	<i>Streptococcus pyogenes</i>	Amoxicillin	In case of <i>Vibrio vulnificus</i> : cefotaxime Plus doxycycline
Cellulitis ^a	<i>Staphylococcus aureus</i> , <i>Streptococcus pyogenes</i>	Amoxicillin, clavulanat As alternatives: Fluoroquinolones, macrolides, and lincosamides	In case of <i>Aeromonas hydrophila</i> : Ceftazidime plus gentamicin In case of MRSA: glycopeptides and newer antimicrobial options (linezolid, daptomycin, telavancin, and tigecycline)
Surgical site ^a infections	<i>Staphylococcus aureus</i>	Amoxicillin/clavulanate Ampicillin/sulbactam	In case of MRSA: glycopeptides and newer antimicrobial options (linezolid, daptomycin, telavancin, and tigecycline)

Whenever the lesion size is $\geq 75\text{cm}^2$ it is classified as ABSSSI.

BHS, β -hemolytic streptococci; MRSA methicillin-resistant *S. aureus*; TMP-SMX.

^aDalbavacin and tedizolid have been approved for their empirical treatment.

Table 3 Empiric antimicrobial therapy for chronic SSTIs.

Infection	Route of administration	Antibiotic/dose	Alternative/dosage
Mild	Oral	Levofloxacin 500 mg od Amoxicillin/clavulanic acid 100 mg BID/TID	Cotrimoxazole 800/160 mg BID/TID
Moderate	Intravenous (possible switch to oral)	Ampicillin/sulbactam 1000 mg QID Ertapenem 1000 mg od Tigecycline 50 mg (with loading dose)	Piperacillin/Tazobactam 4,5 g TID Linezolid 600 mg BID Daptomycin 300/500 mg od
Severe	Intravenous	Clindamycin 600 mg TID plus Ciprofloxacin Imipenem 500 mg Meropenem 1000 mg TID Clindamycin 600 mg TID plus Amikacin 1 g od plus Ampicillin mg ² g TID	Clindamycin 600 mg TID plus Ceftazidime 2 g TID Vancomycin 1 g BID Linezolid 600 mg BID Linezolid 600 mg BID plus Aztreonam 2 g TID plus Metronidazole 500 mg TID

BID = twice a day; TID = three times a day; QID = four times a day.

against common pathogens such as *S. aureus* and BHS and have a convenient once- or twice-daily dosing schedule. Ceftriaxone is most frequently used, with teicoplanin, vancomycin, and daptomycin reserved for SSTIs with suspected or proven methicillin-resistant *S. aureus* (MRSA) etiology. A study evaluating patients suffering with cellulitis who were receiving antibiotics following an OPAT program demonstrated that hospitalization occurred in 7% only of the patients and mean duration of the treatment was days. Analysis of a multivariate model established that age, peak C-reactive protein (CRP) level and number of medical reviews during OPAT therapy were found to be associated with longer duration of IV therapy. Eighty-nine percent of the patients were discharged on oral therapy. Ceftriaxone was the antibiotic administered with the highest frequency (Palit et al., 2021; Esposito et al., 2016b).

Acute non-necrotizing infections: Therapy

Impetigo

Impetigo, which is most often due to *S. aureus*, can be usually treated topically with mupirocin or chlortetracycline twice daily for 5 days. Oral therapy can be a 7-day regimen with an antistaphylococcal penicillin or cephalexin. When MRSA is suspected or confirmed, doxycycline, minocycline, clindamycin, or sulfamethoxazole trimethoprim (SMX-TMP) report similar efficacy in terms of favorable outcome. It remains unclear if oral antibiotics are superior to topical antibiotics, and the therapeutic choice remains an individual decision mostly based on the number of lesions and their location. Based on a systematic review comparing different guidelines for impetigo treatment, a systemic antibiotic therapy is always recommended, and 20 guidelines (39%) do not mention an antiseptic treatment (Hall et al., 2021).

Furuncles and carbuncles

Furuncles' treatment choice is based on lesions dimension as small furuncles can be treated with warm compresses to promote drainage, whereas larger furuncles and carbuncles and all abscesses require incision and drainage. Empiric antibiotic therapy with an anti-staphylococcal (and an anti-MRSA activity in areas of high prevalence) antibiotic can be considered as part of these lesions' treatment. A systematic review on different treatment strategies for furuncles and carbuncles failed in retrieving randomized controlled trials assessing the efficacy and safety of topical antibiotics versus antiseptics, topical versus systemic antibiotics, or phototherapy versus sham light for treating bacterial folliculitis or boils. All the studies tailored to compare different antibiotic treatments did not find a significant difference in terms of efficacy and safety evaluating different antibiotics investigated (Lin et al., 2021).

Recurrence of furuncles can be prevented by using soap containing chlorhexidine gluconate with isopropyl alcohol and a 1- to 2-month course of low-dose oral clindamycin (150 mg daily).

Animal and human bites

Antibiotic administration for those reporting an animal or human bite depends on the severity of lesion, its location, and type. Pre-emptive antibiotic therapy is generally recommended for those wounds at risk of infection. Such therapy must be done with oral amoxicillin/clavulanate or ampicillin/sulbactam after accurate cleaning and copious irrigation. As a general concept, antibiotic treatment should consider both aerobic and anaerobic coverage looking at the bacteria that colonize the skin and the oral environment. In the case of severe wounds, especially in patients with co-morbidities (immunodepression, diabetes, end-stage liver disease) or patients with clinical signs of systemic infections (sepsis), parenteral therapy with piperacillin/tazobactam or carbapenem is recommended due to the risk of an infection sustained by MDR bacteria such as *Pseudomonas* (Greene and Fritz, 2021).

Cutaneous abscesses

Prior to an antibiotic treatment, incision and drainage of pus and debris of cutaneous abscesses is strongly recommended as primary management to reduce the bacterial burden and to allow microbiologic investigations. Needle aspiration - even ultrasonographically guided - should not be performed due to its low rate of success (Kamath et al., 2018).

Concomitant administration of antibiotics does not modify the patient's outcome for localized and small abscesses, but in case of major abscesses, the administration of antibiotics effective against *S. aureus*, which is the main pathogen responsible, is recommended, especially in the presence of clinical symptoms of sepsis, such as temperature $>38^{\circ}\text{C}$, tachypnea, tachycardia, or white blood cell count above $12,000/\text{mmc}$. A placebo-controlled study evaluating the efficacy of antibiotic treatment for small size abscess ($<5\text{ cm}$) demonstrated that in these cases antibiotic administration can be effective if *S. aureus* is cultured (Daum et al., 2017). If an MRSA is suspected, as in geographic areas with a high prevalence of community-associated MRSA (CA-MRSA), or the case of MRSA isolation by cultures, treatment should consider an oral agent, such as TMP-SMX, clindamycin, tetracyclines, oxazolidinones, and fusidic acid. All these antibiotics can be administered in the outpatient setting either after a course of intravenous antibiotic or as first-line therapy (Giacobbe et al., 2021).

Erysipelas

Erysipelas is always caused by *Streptococcus pyogenes*, which is the pathogen in most of the cases responsible for this infection. As *S. pyogenes* has remained sensitive to penicillin over time, this class of antibiotics remains the first choice in establishing a therapeutic plan. Although coverage against *S. aureus* has been proposed, the recommendation for this coverage is weak and based on low-quality investigations. The route of administration - oral or intravenous will be defined according to the severity of the infection. Amoxicillin is the best choice, but also first- and second-generation cephalosporins can be an easy to administer alternative (Karakonstantis, 2020).

Cellulitis

Cellulitis can be a serious infection requiring appropriate antibiotic treatment, such as amoxicillin/clavulanate (oral or intravenous, depending on the disease severity), which is active against the most frequent responsible microorganisms (*S. aureus* and *S. pyogenes*). The therapy must be initiated promptly, monitoring the clinical evolution, and keeping in mind that other pathogens can be present. Fluoroquinolones and lincosamides can be an appropriate alternative even though the resistance to clindamycin is increasing and side effects of fluoroquinolones should be considered. High rates of macrolide/azalide resistance among BHS present in some areas of the world makes use of these drugs a concern, unless susceptibility results are available. If additional bacterial species are likely to be involved after unusual exposures, such as abrasion or laceration occurring after saltwater exposure, where *V. vulnificus* might be the pathogen, treatment with cefotaxime plus doxycycline is effective (Raff and Kroshinsky, 2016).

Similarly, in the setting of cellulitis after an abrasion or laceration occurring with freshwater exposure, where *A. hydrophila* could be suspected, treatment with ciprofloxacin (along with an antimicrobial targeted to the common pathogens) is indicated. When severe lesions are present, a combination of ceftazidime plus gentamicin can be suggested to ensure the best coverage against Gram negative bacteria. If MRSA is suspected (both hospital-acquired and CA-MRSA), glycopeptides, TMP-SMX, and newer antimicrobial options, including linezolid, daptomycin, telavancin (only available in the United States), and tigecycline, are suitable agents. Although several studies investigate the effectiveness of different antibiotic treatments, data regarding route and duration of treatment cannot be considered conclusive, because data beyond 30 days of follow-up available are not sufficient and data regarding side effects of prolonged treatments are not always reported (Walsh et al., 2016; Cross et al., 2020).

Surgical site infections

Similarly, to cutaneous abscesses, treatment of SSIs is based on incision and drainage, which remain the most important aspects of therapy.

Adjunctive systemic antimicrobial therapy should be administered, especially when a significant systemic response is present, as in the cases presenting with fever or signs of sepsis. Antibiotic treatment recommendations are based on the site of operation, considering that *S. aureus* remains the most frequent etiologic agent. Thus, an anti-staphylococcal agent should be preferred, such as amoxicillin/clavulanate or ampicillin/sulbactam, with the route of administration depending on the general conditions of the patient. Whenever the prevalence of methicillin resistance is high, an anti-MRSA is mandatory, with glycopeptides being the gold standard of therapy, although several newer antibiotics have demonstrated similar efficacy in terms of success rate (Norman et al., 2016; NICE, 2015).

ABSSSI

Recently, as noted earlier, the US FDA introduced the new definition of ABSSSI to define cSSTI more closely for the purpose of registration trials.

The new drugs for ABSSSI have important activity also against MRSA, especially dalbavancin and tedizolid. Consequently, these new drugs can be used for prompt empirical treatment of ABSSSI.

Tedizolid, which has long half-life, can be administered once a day only, giving an advantage in terms of compliance to therapy. Dalbavancin was approved by the FDA and EMA with a two-dose regimen of 1000 mg followed 1 week later by 500 mg administered intravenously over 30 min. One of the strengths of dalbavancin is the prolonged half-life which leads to the possibility of a single 1500 mg intravenous (IV) administration, finally shortening the hospitalization period and avoiding the problems related to low compliance to treatment (Hsu et al., 2021; Lan et al., 2019).

Chronic non-necrotizing infections: Therapy

DFIs, pressure ulcer infections, burn infections, and infected chronic ulcers are distinct clinical entities that have the common characteristic in that they can become chronic with a high degree of colonization from the bacteria present in the surrounding environment. These microbiologic characteristics are relevant as bacteria involved can acquire resistance, which is often against multiple antibiotics and can limit the choices for both empiric and subsequent microbiologically driven therapy (Lemaire et al., 2016).

Initial therapy must be empirical in many cases, such as those occurring after burns. A careful evaluation based on the severity of the clinical presentation and on the history of previous antibiotic treatment guides the empirical treatment, which must be changed looking at the microbiologic investigations (Table 3). The spectrum of antibiotic therapy should be broad, considering the possible polymicrobial etiology and should include coverage for *S. aureus*, considering an anti-MRSA agent in those areas with high prevalence of methicillin resistance. Moreover, coverage against Gram negative bacilli is mandatory in all cases with moderate to severe infection and in those failing narrower-spectrum treatment. After culture from tissue biopsy are available, the antibiotic spectrum can be narrowed according to the results. The quality of the specimen should be considered when deciding which isolates need to be covered (Hill et al., 2021; Sakabe and Del Fiol, 2016).

In most cases, treatment of the most likely pathogens, such as *S. aureus*, streptococci, and any *Enterobacteriaceae* provides effective coverage. When cultures are obtained, therapy should be tailored with respect to microbiologic findings. When a fungal infection can be suspected based on histopathology, cultures must be attempted to identify those fungi whose coverage is not provided after amphotericin B administration (Ertuğrul et al., 2020).

Among patients with a recent ineffective treatment, an infection due to MDR microorganisms should be suspected. In these cases, alternative therapies should be administered: vancomycin, linezolid, or daptomycin for MRSA infections; colistin or tigecycline for MDR Gram-negative microorganisms. Antibiotic treatment can be administered in patients with pressure ulcers, but only based on the presence of local or systemic clinical signs of sepsis and after an intensive local curettage (Goei et al., 2020).

Treatment of burn injuries must consider early excision followed by grafting to reduce infection risk and length of hospital stay restoring a barrier against bacteria present in the hospital environment, which frequently report a high degree of resistance to antibiotics; these surgical procedures are an essential part of a burn patient's management. Topical antibiotics are currently employed; their utility can differ with respect to preparation, as demonstrated for silver-sulfadiazine. Antibiotic prophylaxis appears to have no significant value except in those with more severe injuries (Wang et al., 2018).

Chronic trophic ulcers need surgical treatment of vascular complications and control of underlying predisposing factors such as hyperglycemia to ameliorate the outcome. Once infection is diagnosed, chronic ulcers must be treated aggressively. Treatment includes debridement, surgical drainage of abscesses, debridement of infected bone, and tissue culture-guided antimicrobial therapy. Although a lot of topical therapies/antimicrobials and dressings have been proposed for the treatment of chronic ulcers, very few have prospective data to support their effectiveness in promoting chronic ulcer repair (Ertuğrul et al., 2020).

Necrotizing infections: Therapy

All necrotizing SSTIs (myositis, myonecrosis, necrotizing fasciitis, and Fournier gangrene) require immediate surgical debridement because prompt surgery ensures a better likelihood of survival. Surgical debridement must be continued until tissue necrosis ceases and the growth of fresh viable tissue is observed. In addition, an early surgical treatment minimizes tissue loss, reducing the risk for amputation of the infected extremity. Surgical intervention may be required to ultimately confirm the diagnosis and the severity of illness, and lack of evolution control requires immediate surgery before a diagnosis is confirmed by diagnostic investigations. Empiric antibiotics should be started immediately as well (Table 4). Initial antimicrobial therapy should be broad-based to cover aerobic Gram positive and Gram negative organisms and anaerobes, with the highest tolerable doses of the antibiotics considering the patient's weight and liver and renal status. Empiric antibiotic therapy can be employed until wound culture isolates are identified. Acceptable monotherapy regimens include carbapenems, piperacillin/tazobactam, or tigecycline (Jung and Eckmann, 2019).

However, an optimal choice in the management of necrotizing fasciitis can also be the association of ampicillin/sulbactam plus clindamycin and ciprofloxacin or gentamicin. In cases of suspected MRSA infection, TMP-SMX, vancomycin, or daptomycin can be used; alternative drugs include the newer compounds linezolid, tedizolid, dalbavancin, and ceftaroline, although large scale data on these pathogens are lacking. The association of ceftazidime/avibactam or similar agents with an anti-anaerobic agent

Table 4 Empiric antibiotic treatment of necrotizing infection.

Necrotizing infection	Antibiotic choice
Synergistic (aerobic and anaerobic pathogens)	Imipenem, Meropenem, Piperacillin/Tazobactam As alternative: ampicillin/sulbactam plus clindamycin and ciprofloxacin or gentamicin ^a
Penicillin allergy (skin rash only)	Cefepime + metronidazole
Penicillin allergy (anaphylaxis)	Ciprofloxacin + metronidazole
If MRSA is suspected	Vancomycin or daptomycin
If CA-MRSA is suspected	Clindamycin, TPM-SMX
New anti-staphylococcal (including MRSA) alternatives	Linezolid, Tedizolid, Dalbavancin, Ceftaroline
Difficult to-treat gram-negative bacteria	Ceftazidime/Avibactam

^aConsider the patient's renal function CA-MRSA, TPM-SMX.

(metronidazole or clindamycin) can be a useful option in the case of difficult-to-treat Gram-negative bacteria such as an ESBL-producing strain and/or MDR *Pseudomonas* (Urbina et al., 2021).

Hyperbaric oxygen has been reported to reduce associated tissue loss and mortality and is considered an essential part of these patients' management in many cases. Anyway, well-controlled, randomized clinical trials demonstrating a statistically significant benefit of hyperbaric oxygen are difficult to be proposed, and consequently, its use as an adjunctive therapy for necrotizing fasciitis remains controversial. Thus, the mainstay of treatment remains surgical debridement, and this should never be delayed while arrangements for hyperbaric oxygen treatments are being made (Peters et al., 2020).

Superficial fungal infection (SFI) is one of the most frequent forms of infection worldwide (Havlickova et al., 2008; Hay et al., 2014; de Hoog et al., 2017) with prevalence of more than 20%.

The dominant causative agents of this infection are dermatophytes, the group of fungi which invade the keratinized tissue of mammals (Hay et al., 2014; Otašević et al., 2018). In addition to dermatophytes, SFI are often caused by *Malassezia* yeasts (Barac et al., 2015) and *Candida* spp. (Otašević et al., 2016). Moreover, yeast of *Cryptococcus* spp. (Noguchi et al., 2019), *Trichosporon* spp., could cause this form of mycoses primarily in immunocompromised patients. Recently, there has been an increase in published data on the pathogenic potential of non-dermatophytic molds as *Aspergillus* spp., mucorales, the hyalohyphomycetes and dematiaceous fungi in SFI, not only in immunodeficient patients, but also in immunocompetent subjects (Brandt and Warnock, 2003; Kuruvilla and Dias, 2012).

Dermatophytes

Etiology

Dermatophytosis is one of the most prevalent skin diseases due to dermatophytes infection. Classification, or in other words differentiation and identification, of genus and species of this group of fungi were initially based on their morphological characteristics (Sabouraud, 1910; Gräser et al., 1999). However, no standardization, possibility of determination of species only when fresh isolates are examined followed by need of reference strains are the problems when conventional methods are used in process of identification of strains.

The first attempt in effort to overcome these deficiencies was introduction of assays for determination of physiological parameters of dermatophytes. Unfortunately, this approach has limitations too (Weitzman et al., 1983).

Recently, the molecular methods were established and it can be said that it revolutionized dermatophyte taxonomy (Gräser et al., 2000; Makimura et al., 1999; Rezaei-Matehkolaei et al., 2014; Sharma et al., 2006). In one of the newest proposed taxonomy, de Hoog et al. (2017) state, “the number of genera in dermatophytes group has increased (*Trichophyton*, *Epidermophyton*, *Nannizzia*, *Microsporium*, *Lophophyton*, *Arthroderma*, *Ctenomyces*, *Guaromyces* and *Paraphyton*), but species that are relevant to routine diagnostics now belong to smaller groups, which enhances their identification”.

However, in medical mycology the most important are genus *Trichophyton*, *Epidermophyton*, *Microsporum*. Very important differences between mentioned species are their natural habitat. Regarding natural habitat, dermatophyte species are classified in three ecological groups: anthropophilic, zoophilic, or geophilic, where some species are still unclassified due to insufficient data (Ajello, 1962; Weitzman and Summerbell, 1995; Georg, 1960).

Anthropophilic species naturally colonize humans, but rarely animals (de Hoog et al., 2017); in this group, human to human (direct contact or indirectly through contaminated objects) transmission is present; usually cause chronic, mild, noninflammatory infections; the changes on the skin are usually hyperemic with desquamation, sharply demarcated from the healthy tissue, on the hairy part of the head there are small beaches with superficial desquamation, similar to dandruff, while the hair is thinned; minor or major epidemics may occur in collectives. The dominant species all over the world are *Trichophyton violaceum* (*T. violaceum*), *T. tonsurans*, *T. soudanense*, *Microsporum (M.) audouinii*, *Epidermophyton (E.) floccosum* (Otašević et al., 2019).

Zoophilic species parasitize animals, but can infect humans, transmission to humans usually occurs through symptomatic or asymptomatic animals-reservoirs; Mostly species *M. canis*, *T. mentagrophytes*, *T. verucosum* are causative agents; cause strong inflammatory processes, can cause chronic infection that usually takes a long time to treat, sometimes up to a year, not frequently, this infection is accompanied by fever and regional lymphadenitis. After healing, they can cause scarring and permanent alopecia. There is no interhuman transmission except in extremely rare cases (Chmel, 1980; Mayr, 1989).

Geophilic species live in the soil and sporadically lead to human infection; in addition to the soil as a reservoir, they are often found on the fur of animals; in the case of infections, geophilic just like zoophilic species cause acute, inflammatory mycoses in humans, while most infections are quickly resolved (Feuerman et al., 1975; Otašević et al., 2011, 2018).

Clinical manifestations

Based on the literature data, virulence factors of dermatophytes include: (i) adhesion factors that allow fungal spores to bind to the most superficial layer of the skin; (ii) a sulfite pump that allows fungi to cleave disulfide bonds in keratinized tissue, which enables the decomposition, and lyses of proteins; (iii) keratinase production and other proteinases that hydrolyze keratin; (iv) immunomodulatory structures in the composition of the cell wall that suppress the cellular immune response (Weitzman and Summerbell, 1995).

Superficial dermatophytosis is characterized by a slow but constant development of the infection. The changes are sharply demarcated from the healthy skin, accompanied by dandruff, without or with weak inflammation if SFI is caused by anthropophilic species. The most common zoophilic species can cause deep infections that affect the dermis, with a pronounced inflammatory response thus they are manifested by painful pustules, abscesses and lymphadenopathy (Weitzman and Summerbell, 1995; Nenoff et al., 2014).

Symptoms and signs i.e., clinical findings in patients with dermatophytosis depend on the location of the infection, the causative species as well as the immune status of the host.

Tinea pedis

The most common causative agents of *t. pedis* are *T. rubrum*, *T. interdigitale*, *E. floccosum*.

Clinical manifestation: The clinical picture is not pathogen-specific, it can be acute but frequently turns into a chronic form. Intertriginous form localized in the interdigital space is usually associated with onychomycosis (Bardazzi et al., 2013; Piccardo-Geisinger et al., 2014). This form is characterized by maceration, dandruff, itching, vesicle formation and later with burning sensations and pain. Secondary bacterial infections often occur. In addition, the hyperkeratotic type of *tinea pedis*, Moccasin-type *tinea* caused by *T. rubrum* and the third variant the inflammatory vesiculobullous or dyshidrotic type are also described (Romano et al., 2006; Boboschko et al., 2005; Canavan and Elewski, 2015).

Risk factors: *T. pedis* and onychomycosis are becoming more common as a result of changes in lifestyle, including increased urbanization, the use of communal bathing facilities, and occlusive footwear. The increasing incidence of diabetes and HIV infection are also important contributory factors. Certain occupations (miners, soldiers) and recreational activities (marathon runners) predispose *t. pedis* (van der Snoek et al., 2013).

Tinea manuum

The most common causative agents of *T. manuum* are *T. rubrum*, *T. interdigitale*, *E. floccosum*.

Clinical significance: occurs more rarely than *t. pedis*; infection is the most often localized on the palms; it is manifested as a hyperkeratotic form, but can be developed to more severe forms with the appearance of vesicles, maceration, ragads. In addition to this form, intertriginous form occurs very often due to *E. floccosum* infection (Weitzman and Summerbell, 1995; Nenoff et al., 2014).

Risk factors: *T. manuum* occur in people whose profession predispose infection such as bakers, cooks, bartenders. In both *t. pedis* and *t. manuum*, poor hygiene has significant effect on the occurrence of infection (Zhan et al., 2013).

Rarely, *tinea manuum* occurs in bullous form- Bullous *tinea* (Aste et al., 2005). The most common causative agents are *T. rubrum*, zoophilic *Trichophyton* species, as well as *Arthroderma benhamiae*. Clinical examination reveals erythematous-squamous plaques with blister formation. Diagnosis includes detection of fungal hypha forms in PAS stained tissue sections. However, in the beginning of disease, conventional mycological examination can provide confirmation of infection.

Tinea corporis

The most common causative agents: *T. rubrum*, *T. interdigitale*; zoophilic dermatophytes *M. canis*, *T. verrucosum* in children and young adolescents; *T. violaceum*, *M. audouinii* in Africa *T. concentricum* in Southeast Asia Africa and South America (Weitzman and Summerbell, 1995; Nenoff et al., 2014; Otašević et al., 2019; Nenoff and Haustein, 1997).

Clinical significance: Changes are called Herpes tonsurans or ringworm. They occur on the skin, and spread slowly but steadily, most often in circular manner. Lesions are clearly demarcated from healthy skin by an erythematous rim with different types of skin efflorescence, such as papules, vesicles, pustules and crusts, appearing on the affected area, depending on the degree of inflammation. In the center of the change, lighter fields with less pronounced desquamation can be seen. The change is often accompanied by itching of varying intensity. Atypical lesions are seen in immunocompromised patients. Zoophilic species can cause intense inflammation with severe folliculitis.

One of the forms is *t. inguinalis* characterized by macerated and scaly lesions. It is so-called “eczema marginatum” and *T. rubrum*, *T. interdigitale* and *E. floccosum* are dominant causative agents (Bonifaz and Vázquez-González, 2011; Seebacher et al., 2008).

T. glutealis frequently misdiagnosed as anal dermatitis, is characterized by inflammatory follicular papulopustules with typical erythematous-squamous plaques with prominent margins (Ely et al., 2014).

Risk factors: The most common infections in prepubertal children are *T. corporis* and *T. capitis* (Ely et al., 2014). Additionally, diabetes mellitus, long-term treatment with antibiotics or immunosuppressives, compromised peripheral circulation, wearing inadequate synthetic clothing, hyperhidrosis, elevated body mass index, poor personal hygiene and in case of infection by zoophilic species keeping pets or engaging in livestock farming (Weitzman and Summerbell, 1995; Nenoff et al., 2014; Otašević et al., 2018).

Tinea barbae and capitis

The most common causative agents of *T. barbae* and *T. capitis* are zoophilic dermatophytes *M. canis*, *T. mentagrophytes*, *T. verrucosum* (Havlickova et al., 2008; Rodríguez-Cerdeira et al., 2021; Kovitwanichkanont and Chong, 2019).

Clinical manifestation: it is an infection commonly involving the scalp and the beard area, and may be superficial or a severe inflammatory form (Kovitwanichkanont and Chong, 2019). Mild form is usually subclinical and appears as slight erythema and a few patchy areas of scalp with dull gray hair stumps. Contrary, highly inflammatory reaction manifests with folliculitis, kerion formation, and, sometimes accompanied by fever, malaise, and regional lymphadenopathy. Both the skin surface and hairs are involved which can lead to extensive areas of scarring and alopecia. Such infections on the scalp are called *Kerion celsi*, and on the men's beard *Sycosis barbae* (Rodríguez-Cerdeira et al., 2021; Weitzman and Summerbell, 1995; Nenoff et al., 2014; Otašević et al., 2018).

Favus or tinea favosa is a severe and chronic inflammatory dermatophyte infection, due to *Trichophyton schoenleinii* infection. This form of tinea capitis has become a history, except in some areas in Eurasia and Africa. Clinically, favus is characterized by scutula (yellow saucer-shaped crusts composed of epithelial debris and fungal mycelia formation) around hair follicles. Disease is manifested by severe scarring alopecia, and besides scalp, it may affect the glabrous skin and nails (Rippon, 1985; Kwon-Chung and Bennett, 1992; Daadaa and Ben Tanfous, 2020).

Tinea incognito/tinea atypical, unrecognized tinea, by definition is a dermatophyte infection that has lost its typical clinical appearance. It frequently occurs due to: (i) uncritical use of topical corticosteroids or calcineurin inhibitors; (ii) improper treatment; (iii) self-medication; (iv) the lack of differential diagnostic consideration of SFI (Seitz et al., 2013; Zisova et al., 2013).

It should be point out that there has been a worldwide increase in *T. incognito* incidence. Clinically, pruritic erythematous and erosive lesions, often described as eczema-like and psoriasis-like are seen in these patients and often occurs on the trunk and face. *T. rubrum* was found to be the most common causative agent (Kim et al., 2013), but *M. canis* was also described as the pathogen (Amano et al., 2013). The general opinion is that if in patients with *t. pedis* or onychomycosis, eczema-like dermatoses develop on the trunk or face, *T. incognito* occurrence should always be considered.

Trichophyton rubrum syndrome represents a chronic and generalized dermatophytosis with at least four body sites are affected: feet (plantar), hands (palmar), nails, as well as one other site. Depending on the used criteria, syndrome is diagnosed by mycological analyses-detection of fungal elements using mycological examination of material from four sites or cultivation of *T. rubrum* from material from three sites, where in both used criteria inguinal region explicitly has to be excluded (Piñeiro et al., 2010).

Majocchi granuloma (granuloma trichophyticum) is a chronic (Matthes et al., 2001) superficial dermatophytosis in which comes to the appearance of granulomatous follicle-associated inflammatory reaction as a complication of fungal infiltration along hair follicles. The skin lesions are pruritic, erythematous-squamous plaques with follicular papules and pustules and this form of dermatophytosis affects immunosuppressed patients (Steiner et al., 2012). In the most cases of Majocchi granuloma, *T. rubrum* is the causal pathogen, but *T. tonsurans* is also described (Kurian and Haber, 2011).

Dermatophytids or mycids, so-called ID reaction is a consequence of induced, type IV hypersensitivity reactions to dermatophyte components, very frequently as a result of antimycotic treatment (Ilkit et al., 2012). The localization of the lesions is far from the primary dermatophytes infection; they can be as popular or as nodular and multiform eruption. Fungi cannot be isolated from these changes and dermatophytids are remediated when primary fungal infection is cured (Romano et al., 2006; Cheng et al., 2011).

Mycological analyses-diagnostics of superficial fungal infection caused by dermatophytes

Specimen collection

For mycological analyses adequate specimen collection, transport and storage is of crucial importance. The most important principles during specimen collection are:

- The use of aseptic technique
- The material should be sampled appropriately -from the appropriate place (for all infection the material is sampled from the periphery of the change, except in the case of Pityriasis versicolor infection when material for mycological analyses is sampled from the central part).
- Material has to be sampled before starting empirical therapy
- Extra care should be taken if sharp scalpel blade or scissors are used to collect samples
- The quantity of sampled material must be sufficient for all analyses
- The material must be accompanied by clinical findings
- Sacrifices and hair/hairs must be transported in dry sterile containers or envelopes (to prevent bacteria and/or mold overgrowth) which are put in sealed plastic bags
- In case of skin and hair samples, direct inoculation in media for cultivation is recommended immediately after sampling. However, if that is not possible, fast transport, in a period of 2 h, is considered optimal for successful mycological analyses
- The hairbrush technique is favored over scalp scraping in *T. capitis* when causative agents are anthropophilic dermatophytes. On the contrary, epilation of hairs and simple swabs are preferred in purulent infections (Nasir et al., 2014; Nenoff et al., 2014).

Microscopic examination

Despite the efforts for introduction of rapid, non-culture-based assays, the microscopic examination (ME), as user-friendly and rapid method, is irreplaceable for detection of fungi in patient's material. Wet mount with chlorolactophenol or KOH is still convenient technique for screening and direct microscopy examination provides rapid detection of fungal blastoconidia-yeast and pseudohyphal-hyphal forms in patient's material (Figs. 1 and 2) (Brooks et al., 2013; Otašević et al., 2011, 2018). Additionally, specific staining with chemicals or fluorescent dyes can improve visualization and detection of fungi (Arsić-Arsenijević et al., 2012). Calcofluor white binds to the chemical structures (cellulose and chitin) of the cell wall so using the fluorescent microscopy fungal elements could be easier detected.

Culture method—The propagating method

Cultivation and isolation of the causative agent is superior, yet time-consuming procedure that enables antigen-detection, genetic and biochemical identification of etiological agents. In addition, it also allows antimicrobial susceptibility testing.

Dermatophytes can be cultivated on selective media that contain the higher concentration of carbohydrates and antibacterial dugs which prevent bacterial growth and cycloheximide (Actidion®) to suppress mold growth. The optimal temperature for cultivation is 28 °C, and incubation last for three (or four) weeks. Since the time of incubation is so long, growth of fungi is visually checking twice weekly (Nenoff et al., 2014; Arsić-Arsenijević et al., 2012; Otašević et al., 2011). Depending on laboratory equipment, even some selective media, such as dermatophytes test media (DTM), can be used. This particular agar reveals

Fig. 1 Chlorine lactophenol wet microscopic preparation showed spores in the hair.

Fig. 2 Chlorine lactophenol wet microscopic preparation showed numerous spores in the scarification of the skin.

Fig. 3 Whitish-yellow fluffy colony of species *Microsporum canis* on Sabouraud dextrose agar.

dermatophytes growth by color changes from yellow to red due to production of alkaline metabolites. However, in this way the pathogens natural pigment, which is important for identification of species, may be masked. Thus, simultaneous cultivation on both Sabouraud agar and DTM remains mandatory (Figs. 3 and 4).

The differentiation of dermatophytes is based on macroscopic and microscopic morphological characteristics. Macroscopic characteristics include appearance, structure and pigmentation of vegetative and reproductive mycelium (visualization of upper and bottom side of colonies), and growth rate. Microscopic morphological characteristics as sporulation type—formation of macro and microconidia, growth rate schedule and appearance of hyphae are crucial in differentiation of dermatophytes (Fig. 5) (Otašević et al., 2011).

In addition to fungal morphology analysis, physiological tests such as in vitro hair perforation test, hydrolysis of urea, subcultivation on special nutrient media and temperature tolerance test can also be useful in differentiation of dermatophytes species (Otašević et al., 2011).

Immunodiagnostic test—Immunochromatographic kits

Since conventional mycological analyses require time and expert knowledge, a lot of effort is put into the design of rapid immunochromatographic tests (Hayette and Sacheli, 2015). One IC strip uses *Trichophyton* antibodies coated with colloidal gold particles to capture antigens of seven different dermatophyte species. When compared with ME, IC shows sensitivity and specificity of up to 80% for detection of dermatophytes in skin and nail samples (Higashi et al., 2012; Noriki and Ishida, 2016; Tsunemi et al., 2014). Although these tests are convenient and rapid method for screening of dermatophytosis, for mycological diagnosis ME and culture are required.

Molecular methods

Over the last 40 years, a large number of molecular techniques have been developed to identify dermatophytes to the level of a genus or species (Otašević et al., 2018). Molecular techniques using different specific primers are capable of accurate discrimination between zoophilic, geophilic and anthropophilic species. There are even studies which imply that these tests may change the whole perspective on taxonomy, ecology and epidemiology of dermatophytes (Cafarchia et al., 2009, 2013; Tamura et al., 2007). Moreover, due to the possibility of identification they caused a “revolutionary change” in the diagnosis of SFI caused by dermatophytes.

Recently published results (Motamedi et al., 2017) showed that real-time PCR with specific pan-dermatophyte primers for detection of the most common species in clinical samples, identify more infected patients than conventional methods. The use of “in-house” or rare commercial molecular tests enabled rapid detection directly in the patient’s sample in just 48 h (Kondori et al., 2010). In addition, developed single-tube qPCR with ITS1 sequences has a design that allows the detection of 11 species of dermatophytes belonging to the genera *Trichophyton*, *Microsporum* and *Epidermophyton* directly in a patient sample (Bergmans et al., 2010; Dhib et al., 2014). Multiplex PCR for the detection of *T. rubrum* and *T. mentagrophytes* in nail samples with chitin synthetazome 1 and ITS primers, proved to be a molecular test with excellent diagnostic performance (sensitivity 95% and specificity 100%). Also, there are new data on the possibility of using the PCR-ELISA method for the fast and accurate detection of anthropophilic species (*T. violaceum*, *M. audouinii*, *T. soudanense* and *T. rubrum*) in the material of patients with tinea capitis, primarily in endemic areas of Africa. Such testing allows rapid diagnosis, application of effective and appropriate therapy, determination of a possible source of infection and application of preventive measures in order to prevent the spread of the causative agent and infection (Wiegand et al., 2017).

Despite the claims of some authors that molecular techniques cannot be a substitute but only a support to conventional diagnostics due to lower sensitivity and lower positive predictive value of 66.5%, development, standardization and commercialization of molecular tests are of great importance for diagnosis of SFI.

Treatment of superficial fungal infection caused by dermatophytes

The first antimycotic drug that was introduced in clinical practice during the middle of the 20th century is griseofulvin. Afterwards, in the 1980s, ketoconazole was started to be used, while eventually, a decade later, fluconazole, itraconazole and terbinafine were developed. The increased resistance of dermatophytes to antifungal drugs, observed in the last few years, raised the interest of researchers. Therefore, many studies have been conducted in order to single out the most efficient antimycotics and to update the therapeutic guidelines for fungal infections (Bishnoi et al., 2018; Khurana et al., 2018).

The effectiveness of systemic antifungals depends on various factors, such as: fungal characteristics (host adaptability, virulence, variation in drug susceptibility, biofilm formation); host factors (immunocompetence); drugs features (mechanism of action, MFC/MIC ratio, absorption, levels achieved in skin, keratin adherence) and finally clinical presentation of SFI.

It appears that resistance established in vitro correlates with therapeutic failure. On the other hand, good in vitro susceptibility does not guarantee favorable clinical outcome (Espinel-Ingroff, 2000). Accordingly, the term recalcitrance is now preferred over the term resistance since it better define in vivo antimicrobial activity by referring to both in vitro resistance and all the other potential contributors to treatment failure (Jones, 1990; Sardana and Khurana, 2018). Dermatophytosis may be treated with azole derivatives, allylamines, griseofulvin, polyenes and others. The azole-derived agents act by inhibiting the lanosterol 14 α -demethylase and that way interfere with synthesis of ergosterol. They represent the biggest group of antifungals which includes both systemic (Fluconazole, Ketoconazole, Itraconazole, Voriconazole, Posaconazole, Isavuconazole) and local (Clotrimazole, Miconazole, Econazole, Luliconazole, Lanoconazole, Efinaconazole, Sertaconazole, Oxiconazole, Eberconazole, Fenticonazole, Bifonazole) agents. Allylamines inhibit squalene epoxidase and also encompass systemic (Terbinafine) and topical (Terbinafine, Butenafine, Naftifine) drug forms. Heterocyclic benzofuran—Griseofulvin was one of the first antimycotic and it inhibits the microtubule aggregation. Polyenes (Nystatin, Natamycin, Amphotericin B) affect cytoplasmic membrane permeability by formation of pores and they can be applied locally. Echinocandins (Anidulafungin, Caspofungin, Micafungin) which inhibit glucan synthesis, have only demonstrated good in vitro effect, however there are still no results from clinical trials.

Apart from mentioned groups of antifungals, following drugs can be used for local application: Morpholine Amorolfine (Inhibition of C-14 reductase and C8 isomerase); Thiocarbamate Tolnaftate (Inhibition of squalene epoxidase); Hydroxypyridones-Ciclopirox (Inhibition of metal dependent enzymes—catalase, peroxidase); Tavabarole (cytoplasmic leucyl tRNA synthetase—inhibition of protein synthesis and termination of cell growth) (Khurana et al., 2018).

Systemic antimycotics being used for dermatophytoses treatment are azoles ITR, FLU, KTZ and allylamine TRB. Over the last three decades, ITR showed favorable results in treatment of dermatophytoses. This drug achieves sufficient concentration in SC, good accumulation, with concentration being higher than in plasma (Cauwenbergh et al., 1988); obtained concentration is maintained for weeks after the therapy; there are no public data of dermatophytes resistance to ITR, except occasional reports of *T. interdigitale* higher MIC (Singh et al., 2018). The common dose is 100 mg for 15 days or 200 mg for 7 days, while the therapy course may be prolonged if the infection is not cured (Khurana et al., 2018; Sardana and Gupta, 2017; Rajagopalan et al., 2018).

Another azole used in treatment of dermatophytoses is FLU, which rapidly accumulates in SC exhibiting high concentration. However due to low binding avidity, concentration is not long lasting (Wildfeuer et al., 1994). Fluconazole is considered effective in treatment of tinea capitis (Gupta and Cooper, 2008). It is prescribed in a dose of 150 mg weekly, given for 2–6 weeks (Stary and Sarnow, 1998; Suchil et al., 1992; Sardana and Khurana, 2018). Unfortunately, it was noted that this weekly regimen may not lead

to clinical improvement (Balci and Cetin, 2008), while several studies established high in vitro MICs (Ghannoum et al., 2006; Gupta et al., 2005; Khurana et al., 2018; Rudramurthy et al., 2018). A study from India reported that almost 50% of isolates were resistant to FLU (Singh et al., 2018) where it is not considered a first-line drug for dermatophytoses anymore.

Ketoconazole has good clinical efficacy, high keratin adherence and steady levels in the SC even 10 days after the end of treatment (Jones, 1990). Additionally there are no reports of resistance while reports of high in vitro MICs are rare (Singh et al., 2018). Nevertheless, due to hepatic toxicity, it is used with caution and restrictions while in some countries its use is completely forbidden (Gupta and Lyons, 2015). The drug is still used locally for superficial mycoses (Gupta and Lyons, 2015) whereas it is sporadically employed in a dose of 200–400 mg/day as a “last resort” option for severe recalcitrant dermatophytoses, with mandatory liver function monitoring.

Allylamine TRB has good penetration to SC mainly because of secretion into sebum and maintains high concentration even after treatment is finished (Faergemann et al., 1991, 1993). It is well tolerated and has minimal drug interactions, hence it is drug of choice for dermatophytoses. Recommended dose is 250 mg, 2–3 weeks, which can be prolonged if needed.

Griseofulvin is the first systemic antifungal used for treatment of dermatophytoses. Regarding its no special binding forces existing to hold GRI in SC (Epstein et al., 1972), GRI require prolonged treatment of several weeks to months. Studies showing resistance of dermatophytes isolates to GRI (Yenişehirli et al., 2013; Mistik et al., 2006) limited the use of GRI to tinea capitis (Gupta and Cooper, 2008).

Topical antifungals that are used for dermatophytosis treatment are shown in Table 1 (Evans et al., 1993; Givens et al., 1995; Goldstein et al., 2000; Noble et al., 1998; Shear et al., 1998).

Epidemiology of dermatophytes infection

The prevalence of certain types of dermatophytes which are causative agents of SFI and the localization of these infections differs depending on the geographical, socio-economic, and ecological characteristics of the region and people's habits and customs in certain areas.

In Asia, *T. rubrum* and *T. mentagrophytes* are the most commonly isolated causative agents of tinea pedis and tinea unguium. The most common causes of tinea capitis are zoophile dermatophytes, species *M. canis* and *T. verrucosum* (Rodríguez-Cerdeira et al., 2021). Also, as a very dominant species causing tinea capitis and corporis, the fungus *T. violaceum* has been proven on this continent (Celik et al., 2003; Lari et al., 2005). Similarly, based on the available data, in Australia, the same species as in Asia are most common causes of tinea pedis and tinea unguium, but (Merlin et al., 1999) in this area of the world, *T. violaceum* as a cause of tinea

Table 1 Local therapy of dermatophyte infections.

Agent	Drug formulation and dosing frequency
<i>Allylamine</i>	
Naftifine	1% Cream once daily
	1% Gel once to twice daily
Terbinafine	1% Cream solution once to twice daily
<i>Benzylamine</i>	
Butenafine	1% Cream once to twice daily
<i>Imidazole</i>	
Clotrimazole	1% Cream, solution, twice daily
Econazole	1% Cream once daily
Ketoconazole	1% Cream once daily
	1% Shampoo twice weekly
Miconazole	2% Cream, spray, lotion, powder—twice daily
Oxiconazole	1% Cream or lotion once to twice daily
Sulconazole	1% Cream or lotion once to twice daily
<i>Other</i>	
Ciclopirox	1% Cream or lotion twice daily
Tolnaftate	1% Cream or solution or powder twice daily

Note. Local therapy is used in *Tinea corporis*, *Tinea pedis* (uncomplicated), *Tinea cruris*, *Tinea manuum* and *Tinea faciei*. capitis has been proven mainly in immigrants from Africa. Additionally, unlike in Asia the predominant causative agents of tinea capitis in this territory are anthropophilic species (*T. soudanense* and *M. audouinii*) (Rodríguez-Cerdeira et al., 2021). In America, the most common dermatophytes are *T. rubrum*, *T. tonsurans*, and *T. mentagrophytes* (Brilhante et al., 2000; Welsh et al., 2006). A dramatic increase in the incidence of *T. tonsurans* infections has been registered, especially among athletes who practice martial arts, which is why the term “Tinea corporis gladiatorum” was introduced. In the United States, *T. rubrum* is the cause of tinea manuum/pedis in 70% of patients (Foster et al., 2004). *T. tonsurans* has been proven in as many as 95% of patients with tinea capitis, after long-term dominance of the anthropophilic species *M. audouinii* (Kemna and Elewski, 1996). In Canada, in a period of only 10 years (1985–96), an incredible increase in the prevalence of tinea capitis also caused by *T. tonsurans* was recorded (Gupta and Summerbell, 1998). In the previous period, the most common causes of superficial mycoses were *T. verrucosum* and *Microsporum* spp. In South America, the zoophilic species *M. canis* and *T. mentagrophytes* and the geophilic species *M. gypseum* are the most common causes of tinea capitis in children (Rodríguez-Cerdeira et al., 2021). *T. rubrum* is the predominant cause of tinea corporis in these areas, and *T. tonsurans* is most common in tinea capitis in adults (Foster et al., 2004). In the central part of the American continent, the species of dermatophytes with the highest prevalence are *T. rubrum*, *T. mentagrophytes*, *M. canis*, *T. tonsurans* and *E. floccosum* (Welsh et al., 2006). Fungal infections are very often diagnosed in Africa. The incidence of tinea in 2005 in Sub-Saharan Africa was around 78 million cases (Hay et al., 2006). The species *M. audouinii*, *T. violaceum*, *T. soudanense*, and *T. gourvilii* are the most common causes of tinea capitis. *T. mentagrophytes* and *T. rubrum* are the most common causative agents of tinea corporis, especially tinea cruris or tinea axillaris in women (Enweani et al., 1996; Ellabib et al., 2002; Abu-Elteen and Malek, 1999).

The most common causes of superficial mycoses in European countries are *T. rubrum*, *M. canis*, *T. mentagrophytes*, and *T. verrucosum*. The dominant causative agents of tinea capitis are *M. canis*, *T. mentagrophytes*, *T. tonsurans*, and *T. violaceum* (Rodríguez-Cerdeira et al., 2021). *T. rubrum* is the most common cause of SFI in urban centers of France, Germany, Switzerland, Finland, and Russia (Foulet et al., 2007; Seebacher et al., 2008; Lehenkari and Silvennoinen-Kassinen, 1995; Monod et al., 2002; Khaldin et al., 2005). In the United Kingdom the predominant species that causes tinea capitis is *T. tonsurans*. After the long-term dominance of *T. verrucosum* in Belgium and the Netherlands, *M. canis* has been recorded as a causative agent of superficial mycoses in recent years in 40% of cases (Korstanje and Staats, 1994). In the countries of Eastern Europe, the Mediterranean, as well as in the countries of the former Yugoslav republics, zoophilic species still dominate, among which *M. canis* is also the most dominant (Nowicki, 1996; Panasiti et al., 2007; Lange et al., 2004; Dolenc-Voljc, 2005; Prohic, 2008; Otašević et al., 2019).

Malassezia spp.

Additionally to dermatophytes group of fungi, *Malassezia* species, lipophilic yeasts, recognized as skin commensals could be the causative agents of skin infection with very high prevalence. These species are capable of producing an extensive array of bioactive indolic compounds especially in pathogenic condition (Gupta et al., 2003) and can cause. Pityriasis versicolor (PV), pityriasis/ *Malassezia* folliculitis (PF) and seborrhoeic dermatitis (SD). Apart from ultraviolet radiation, recent data showed that the presence of different *Malassezia* species, different yeast density and enzyme production, could be important for *Malassezia* role in pathogenesis of melanoma (Vekic et al., 2016). The core mechanism by which *Malassezia* yeasts could probably mediate the carcinogenesis acts through the production of locally acting potent indolic AhR ligands (Gaitanis et al., 2011).

Additionally, there is the evidence that *Malassezia* spp. contribute to the development of atopic dermatitis by T-cell cross-reactivity due to similarity between fungal and human antigens (Nowicka and Nawrot, 2019). However, for explanation of the pathogenetic mechanisms and link between fungi and immune defense further research is required.

In *Malassezia* genus at least 14 different species were differentiated as: *M. furfur*, *M. sympodialis*, *M. globosa*, *M. obtusa*, *M. restricta*, *M. slooffiae*, *M. dermatis*, *M. japonica*, *M. nana*, *M. yamatoensis*, *M. equina*, *M. caprae*, *M. cuniculi* and *M. pachydermatis* (Naldi and Reborá, 2009).

Clinical manifestation

Pityriasis versicolor is SFI caused by *Malassezia* yeast that transform from commensal to pathogen form. Invasion of yeast to stratum corneum influences pathological changes in skin areas. Infection is characterized by round or irregularly shaped macular change with squamation which may be accompanied by lesions, wrinkles and widespread skin may be affected. Lesions are hypopigmented in dark skin or hyperpigmented in white skin individuals. Mild itching may accompany the visible changes (Faergemann, 1993, 2000).

Seborrhoeic dermatitis is eczema where beside genetic predisposition *Malassezia* species may be causative agents. SD is characterized by poorly defined erythematous, flaking, and greasy-looking patches, following by itching in some cases (Schwartz et al., 2013).

Malassezia/pityriasis folliculitis is an inflammatory condition of the sebaceous glands. In spite some evidence of inflammatory reaction which is followed by focal rupture of the follicular epithelium, pathological mechanism is still unclear (Faergemann, 2000; Gupta et al., 2004). A rash of uniform erythematous papules or pustules are often seen in patients (Abdel-Razek et al., 1995).

Diagnosis

The diagnosis is made on the basis of the clinical findings and microscopic examination of skin scraping samples can be taken from the surface of skin (area of 4 cm²) by scraping or using adhesive tape on the skin for 1920s (Pechere et al., 1999). Detection of active reproduction of yeast with forms like meatballs and spaghetti pattern during microscopic examination goes in favor of infection. In Wood's light, that can be used, a bright yellow color may be emitted from the lesions and thus visualize the extent of the affected skin areas. It has to be highlighted that negative Wood's light examination does not exclude PV as not all *Malassezia* species fluorescence (Hald et al., 2015).

For the isolation, selective media as modified Dixon agar (mDIX), Leeming-Notman agar (LNA), potato dextrose agar with olive oil (Oil-PDA) for the isolation of lipophilic species, and standard mycological media Sabouraud dextrose agar (SDA) for the isolation of *M. pachydermatis* can be used. Inoculated media incubated for 10 days at 32 °C under aerobic conditions and growth on culture has to be observed daily (Guillot and Gueho, 1995; Leeming et al., 1989).

A preliminary differentiation of the lipophilic *Malassezia* species can done by detection of colonies on selective media, Dixon and LNA, followed by absence of growth on SDA. Identification of isolated strains included microscopic examination (cell characteristics) and testing of physiological and biochemical characteristics (catalase production and Tween assimilation) (Leeming et al., 1989; Barac et al., 2015). Recently, modified CHROMagar Candida with ox bile, glycerol monostearate, glycerol and Tween 60 as an essential ingredients for *Malassezia* growth, make possible the simultaneous isolation, species differentiation and identification of *Malassezia* and *Candida* species (Kaneko et al., 2005).

Treatment of SFI caused by *Malassezia* spp.

Pityriasis versicolor is usually successfully treated with topical agents that has antimycotic or keratolytic effect. Systemic treatment, alone or in combination with topical antimycotic, is occasionally used in case of serious infection or when local treatment was ineffective (Montero-Gei et al., 1999; Faergemann, 2000; Dehghan et al., 2010; Partap et al., 2004).

It should be kept in mind that sometimes for complete resolution of skin changes several months are needed, especially when hypopigmentation is present. Subsequent mycological analysis is required for confirmation of healing (Drake et al., 1996; Fredriksson and Faergemann, 1983; Hull and Johnson, 2004; Faergemann and Fredriksson, 1980).

Considering high recurrence rate of this infection, different maintenance therapy modalities are proposed. Application of selenium disulfide every 3 months for 2 years is appropriate since it reduces chance of relapse from 82% to 20%. Likewise, the use of ketoconazole 2% shampoo once daily for at least 3 days at the beginning of summer session may also be useful (Piérard-Franchimont et al., 2002; Stratigos et al., 1988).

In case of Seborrheic dermatitis in the majority of patients, local therapy is sufficient. Systemic treatment approach is undertaken when large area of skin is affected or when there is resistance to topical treatment. Most commonly antifungals and corticosteroids are used in combination. The maintenance therapy is frequently required (Peter and Richarz-Barthauer, 1995; Faergemann, 1986; Taieb et al., 1990; Hald et al., 2015).

Data regarding treatment of *Malassezia* folliculitis are limited since studies are done on small number of subjects. It is considered that systemic therapy is more effective than local, although the best results are achieved when these both are combined. Here also, maintenance therapy is preferable in order to avoid relapse. Local antimycotics can be combined with keratolytics (Levy et al., 2007; Abdel-Razek et al., 1995; Jacinto-Jamora et al., 1991; Yu et al., 1998).

Candida spp.

Superficial fungal infection caused by *Candida* spp. can be divided into three distinct entities, intertrigo, paronychia and onychomycosis. *Candida*-intertrigo, as its name implies, occurs on intertriginous areas of skin, namely between fingers or in axillary, pubic and submammary regions (Tasić and Pešić, 2006). The main predisposing factors for this condition are moisture, heat, friction, and maceration. It is especially common among young children living in poor sanitary conditions and elderly people (Yibin et al., 2018; Lane, 1995; Varade and Burkemper, 2013). Typical skin lesions are erythematous plaque with erosions and satellite pustules that have tendency to spread on healthy skin. Chronic forms of infection are part of clinical picture of chronic mucocutaneous candidosis, but may also be seen in other immunodeficiencies (Jautová et al., 2001).

Superficial candidosis (SC) is routinely established using conventional mycological methods specifically ME (cytology) and fungal cultivation. Microscopy is a method that may quickly provide initial diagnosis. Although fast and simple method that enables rapid detection of fungi (blastospores, pseudohyphal or hyphal forms) in the patients' material, microscopy, in the most cases, cannot be used for determination of genus or species (Otašević et al., 2018). In mycological laboratories selective media, Sabouraud dextrose or maltose agar with gentamicin and chloramphenicol, are used for isolation of *Candida* spp. optimal cultivation time of yeast is 48–72 h at 37 °C in aerobic atmosphere. Following their growth on the selective media, yeast are identified through biochemical characteristics. Two tests used for determination of phenotypic characteristic of *C. albicans* species and its differentiation from other species are germination test and chlamydoconidia production test (Savić et al., 2020). Additionally, differentiation of yeast is made using assimilation test. Interpretation of assimilation or other biochemical tests is based on opaqueness or change of indicator color which is done by mycologist or in more advanced laboratories by automatized systems

Fig. 6 Differentiation of three *Candida* species on the basis of colony color during primoisolation: *C. krusei*—pink colony with rough appearance *C. albicans*—green colony, *C. tropicalis*—blue colony.

(VITEC- automatized system) (Arsić-Arsenijević et al., 2012; Otašević et al., 2011). Recently, chromatogenic selective medias allow differentiation of three *Candida* species on the basis of colony color during primoisolation (*C. albicans*—green colonies, *C. tropicalis*—blue colonies, *C. krusei*—pink with rough appearance; Fig. 6). The importance of these media is heightened by the fact that it gives opportunity to diagnose infection caused by different *Candida* species, which is impossible on other medias (Arsić-Arsenijević et al., 2012; Otašević et al., 2011).

Cryptococcus spp.

The yeast of *Cryptococcus* genus may cause skin infection which can be primary or secondary. According to newest classification primary infection is defined as localized infection in the absence of systemic dissemination, cryptococcal fungemia or antigenemia (Noguchi et al., 2019). This form is rare and is usually seen in immunocompromised patients, although it may also develop in immunocompetent hosts thus should be included in differential diagnosis of skin infection (Christianson et al., 2003).

On the other hand, secondary infection is developed as part of disseminated cryptococcosis (Srivastava et al., 2015).

Skin lesions vary from small papules, vesicles, purpura, or acne like lesions while later they may ulcerate and thus cause abscess, erythematous nodules or cellulitis formation (Savić et al., 2020). The lesions are treated with systemic antimycotics.

Patients with cutaneous cryptococcosis should be closely monitored since they are at increased risk of developing disseminated form or CNS cryptococcosis. On the contrary, secondary cryptococcal skin infection in AIDS patients implies dissemination of *Cryptococcus* spp. (French et al., 2002; Jarvis et al., 2009; McKenney et al., 2015).

Nondermatophytic molds

Nondermatophytic molds rarely cause skin infections. However these fungi are widespread, persisting in immediate human surroundings, on soil and other living organisms (i.e., plants or animals), therefore skin infection are possible. Primary infection usually develops on skin damaged by laceration, burns or some medical procedures like cannula insertion, needle puncture and use of adhesive tapes (Douglas et al., 2016; Spesso et al., 2018; Obradovic-Tomasev et al., 2014). Additional risk factors are contaminated tattoos, as well as cosmetic treatment for rejuvenation such as soft tissue fillers (Shin et al., 2017). Wide presence of molds even on walls and floors of buildings contribute to infection especially when construction works are done in hospital or in the surroundings.

Cutaneous nondermatophytic mold infection may also be the result of fungal dissemination which suggest poor prognosis of underlying disease. Besides, in immunocompromised patients, skin infection caused by these fungi may be the source of pathogen dissemination causing fungemia and invasive mold infection (Durand-Joly et al., 2003; Gallais et al., 2017).

The great number of fungal genera are found in the nature. One proposed classification divide infections into two broad groups, those caused by *Aspergillus* species and those caused by non-*Aspergillus* molds. Non-*Aspergillus* SFI can be caused by *Mucorales* fungi, hyalohyphomycetes (bright pigmented fungi) and phaeohyphomycetes (dark pigmented fungi or dematiaceae fungi) (Douglas et al., 2016; Revankar and Sutton, 2010).

Aspergillus SFI: Primary cutaneous aspergillosis is typically seen after the trauma is coupled with contamination by the fungi of *Aspergillus* spp. The lesions are maculopapular yet inflammatory nodules, abscess or necrosis can develop (Frias-De-León et al., 2018; Shin et al., 2017; Gallais et al., 2017).

Mucorales fungi usually produce skin infection in intravenous drug addicts or in those tattooed with the contaminated ink. Additionally, infection also occur following extensive burns (Kang et al., 2014; Spesso et al., 2018; Xu et al., 2018; Devauchelle et al., 2019).

Fig. 7 Characteristic microscopic morphological characteristic of *Aspergillus* spp.: Septate hyphae, hyaline conidiophores with phialides borne directly on the vesicles.

Fig. 8 Microscopic morphological characteristics of *Penicillium* spp.: Conidiophores showing two-stage branching and forming flask shape phialides in groups.

Hyalohyphomycosis are SFI commonly caused by species of genus *Fusarium*, *Scopulariopsis*, *Acremonium*, *Trichoderma* and by species *Penicillium marneffei* (Figs. 7–9). For the last 10 years there has been a significant rise in rate of these infections mainly in patient with neutropenia due to hematological malignancy. If neutropenia is not managed it contributes to failure of antifungal treatment. Multiple red or gray macules along with pustules and subcutaneous nodules with central ulceration are characteristic for *Fusarium* infection (Hay, 2007; Durand-Joly et al., 2003; Bodey et al., 2002).

Acremonium genus comprise of saprophytic molds which often cause problems in laboratory work since they contaminate medium. Skin infection is manifested by pustules and eventually may lead to erythema and edema of large skin area with ulcerations and pus drainage (Sharma et al., 2013; Hilmioğlu et al., 2015).

Scopulariopsis spp., more precisely species *Scopulariopsis brevicaulis*, can induce chronic granulomatous skin condition in both immunodeficient and immunocompetent persons (Wu et al., 2009; Gavril et al., 2016).

In the genus *Penicillium*, species *P. marneffei* is commonly labeled as causative agent of fungal infections, including infections of the skin. This species is, in some parts of the world, the most common cause of fungal infection in AIDS patients (Ungpakorn, 2000).

Over the last few years cutaneous infections presenting as necrotizing ulcer due to *Trichoderma* species have been reported in immunodeficient patients (Román-Soto et al., 2019).

In addition to mentioned non-*Aspergillus* molds, skin infection can be caused by dematiacea fungi. In the literature, reports of the possible pathogens include *Alternaria* spp. (Williams et al., 2008; Gürçan et al., 2009). *Bipolaris* spp. (Ge et al., 2017; Bilu et al., 2004; Dubois et al., 2008) *Cladophialophora bantiana*, *Curvularia* spp. (Moody et al., 2012; Berg et al., 1995), *Exophiala* species (Lucas-Truyols et al., 2019; Espanhol et al., 2019), *Scedosporium prolificans*, *Scytalidium dimidiatum* (Brandt and Warnock, 2003; Xavier et al., 2010). Dematiacea infections occur in immunocompetent subjects and are more common in tropical regions (Neoh et al., 2007; Miyagawa et al., 2017). The changes appear as erythematous or squamous lesions accompanied by rosacea-like popular lesions.

Fig. 9 Microscopic morphological characteristics of *Trichoderma* spp.: Hyphomycete with repeatedly branched conidiophores bearing clusters of flask-shaped phialides.

Fig. 10 Microscopic morphological characteristics of *Fusarium* spp.: characteristic fusiform to sickle shaped macroconidia.

Diagnosis of SFI caused by *Aspergillus* and non-*Aspergillus* molds is made by standard mycological analysis (MI and cultivation) (Figs. 7–12). Furthermore, histopathological examination is considered as the golden standard and is used for confirmation of pathogenic process induced by fungi. Of crucial importance for correct diagnosis is to avoid possible mold colonization, contamination of skin or sampled material. The growth of non-dermatophyte molds should always be investigated further and not automatically regarded as contamination. The best practice is to combine clinical findings and the results of microscopic examination and cultivation which should be successively repeated (Demitsu et al., 2020). Only by such multidisciplinary approach and inclusion of clinicians/dermatologists it is possible to establish the right diagnosis.

Fig. 11 Microscopic morphological characteristics of *Alternaria* spp.: Obclavate, ovoid or ellipsoidal, pale brown multicelled macroconidia with short conical breaks.

Fig. 12 Microscopic morphological characteristics of *Bipolaris* spp.: Development of pale brown, fusiforms to ellipsoidal, pseudoseptate poroconidia.

Trichosporon* spp.; *Piedraia hortae*; *Hortae werneckii

Among members of genus *Trichosporon*, species *Trichosporon* (*T.*) *asahii* or *T. beigeli* as it was previously known, is of the biggest clinical significance (Pulvirenti et al., 2006). It cause the development of whitish nodules adhere to the hair shaft that are referred to as white piedra. On the other hand, black piedra, caused by fungus *Piedraia hortae*, is characterized by black nodules, small in size and firmly attached to the hair (Schwartz, 2004).

The non-contagious, superficial fungal infection named tinea nigra is caused by species *Hortae werneckii* (*Exophiala werneckii*). It is usually seen following an injury on palms and soles as black or brown patchy lesions without scaling (María Consuelo Giordano et al., 2018).

After clinical suspicion, diagnosis is made by detection of fungal elements in the material using microscopic examination. Fungal culture can also be performed with identification of species based on either biochemical (*Trichosporon* spp.) or morphological characteristics (*Piedraia hortae*) (Savić et al., 2020).

Glossary

Antibody Serum proteins, immunoglobulins, that recognize (bind) a specific antigen.

Antigen Molecules that are recognized by antibody molecules.

Autosomal inheritance Inheritance of genes on all chromosomes except the X and Y chromosomes.

Cytokines Proteins made by cells; they bind to specific receptors on other cells and affect their behavior.

Immunoglobulin replacement therapy Is the infusion of Immunoglobulin G obtained from healthy individuals into patients with immunodeficiency either intravenously (directly into the blood stream) or subcutaneously (under the skin).

Opportunistic organism Microorganism that cause disease only in immunodeficient patients such as in AIDS.

Signal transduction Process by which events on the cell surface are translated into changes in the nucleus of a cell; the process usually involves activation of a series of molecules inside the cell, one after the other, until activated molecules move into the nucleus and either turn on or turn off expression from one or more genes.

Stem cell transplantation Also known as bone marrow transplantation is a procedure where bone marrow derived stem cells from a healthy individual are transplanted (infused) into an immunodeficient patient to correct the immunodeficiency.

Thymus An organ located in the chest, just behind the breastbone, where T lymphocytes develop from precursor cells that leave the bone marrow and enter the thymus.

Human primary immunodeficiencies

The main function of the immune system is to protect against invading microorganisms (bacteria, viruses, fungi, and parasites) that cause disease (pathogenic microorganisms or pathogens). In addition, it must destroy any of the body's own cells that develop into cancer. Primary Immune Deficiency Diseases are inborn errors of immunity (IEI) resulting from genetic defects that affect the development or function of one or more components of the immune system, leading to an increased susceptibility to infection and, in some cases, to cancer, autoimmune, inflammatory or allergic disease. These immunodeficiency diseases demonstrate the

importance of each of the altered components of the immune system in immunity. This chapter is organized according to the classification of the International Union of Immunological Societies (IUIS) (Tangye et al., 2020), however, with the large number of genetic defects causing primary immunodeficiency disease, this chapter provides only an introduction to the various types of immune defects with more detailed information found in specific chapters.

Immunity to invading pathogens

The first line of defense against pathogens involves mechanical barriers such as the skin and mucous membranes of the respiratory and gastrointestinal tracts (Janeway and Medzhitov, 2002). Once a pathogen has broken through these barriers, a variety of soluble proteins and phagocytic cells attack the invading pathogen and destroy it. Phagocytic cells are white blood cells (WBC) that can ingest pathogens and play an important role in the early response to an infection. Phagocytes must be able to reach the site of infection and must be able to ingest and kill the pathogen. The initial immune response to an invading pathogen is called the innate immune response and involves the recognition of the pathogen as a danger signal by proteins found on the surface and inside the cell called pattern recognition receptors. The receptors recognize molecules common to all members of a class of pathogen (pathogen-associated molecular patterns, PAMPs) but cannot differentiate between the different pathogens within the specific class. This early response triggers an inflammatory reaction that is necessary for the activation of the adaptive immune system consisting of antibodies secreted by B lymphocytes as well as T lymphocyte responses that can kill infected cells directly, help B lymphocytes make antibody and help phagocytic cells kill intracellular pathogens.

Some pathogens have a cell wall structure that prevents their ingestion by phagocytes. Such pathogens are cleared by antibodies, which recognize specific molecules on the surface of the pathogen (antigen). Antibody molecules recognize the three-dimensional structure of antigen and have at least three basic mechanisms of action: (1) they can directly neutralize toxins, (2) they can kill pathogens by binding to and activating proteins of the complement system, and (3) they can facilitate the uptake of pathogens by phagocytic cells through surface receptors for immunoglobulin (Murphy and Weaver, 2017). A fourth mechanism of action has been discovered and involves high affinity receptor to immunoglobulin (TRIM21) found inside cells (McEwan et al., 2013). Antibodies bound to DNA or RNA nonenveloped viruses or intracellular bacteria bind to this receptor with high affinity and trigger inflammatory and antiviral processes inside the cell. Immunoglobulin molecules have two identical variable regions, antigen-binding sites and a constant region that determines the isotype and function of the immunoglobulin molecule (Murphy and Weaver (2017). There are five major isotypes of immunoglobulin molecules (IgM, IgD, IgG, IgA, and IgE), each with characteristic functions. The main function of antibodies is to clear the extracellular space of pathogens and their toxins (Murphy and Weaver, 2017) as well as some intracellular viruses and bacteria (McEwan et al., 2013). IgM is secreted as a pentamer of five molecules attached to each other. Because of their large size, IgM molecules remain within the blood vessels. IgG antibodies are secreted as single molecules and therefore are found inside and outside of blood vessels, cross the placenta to protect the newborn, and bind to the intracellular immunoglobulin receptor (TRIM21) to clear nonenveloped viruses and some intracellular bacteria. IgA antibodies are secreted as dimers at mucous membranes and in breast milk; they help prevent pathogens from entering through the mucous membranes. IgE antibodies play a role in fighting parasitic diseases, but also cause allergic diseases. When B lymphocytes are first activated by an antigen, they synthesize and secrete IgM antibodies. Immunoglobulin isotype switching, from IgM/IgD to IgG, IgA, or IgE, is the mechanism by which a B lymphocyte can synthesize an antibody with the same antigen specificity (same variable region) but with different function (different constant region, isotype). Isotype switching in human B lymphocytes requires a contact-dependent signal from T lymphocytes (Stavnezer et al., 2008).

Some pathogens, such as viruses, invade cells directly and take over the cell's machinery. While nonenveloped viruses can be cleared by antibody inside the cell, other pathogens including enveloped viruses, remain inside the cell and out of the reach of antibody molecules. T lymphocytes play a key role in clearing such intracellular pathogens by recognizing infected cells and killing them (Murphy and Weaver, 2017). T lymphocytes recognize antigens by antigen receptors on their surface called T cell receptor (TCR). TCRs have a variable region similar to that of immunoglobulin molecules, but are different in that they do not recognize the whole antigen in its three-dimensional structure, they recognize a fragment of the antigen (peptide) in association with (presented by) antigen-presenting molecules on the surface of infected cells. Antigen-presenting molecules are called major histocompatibility complex (MHC) molecules because they determine whether an individual tolerates a tissue graft from another individual. There are two types of MHC molecules: MHC class I and class II molecules. MHC class I molecules are present on all cells, present peptide fragments from proteins that are produced by a virus-infected or cancer cell and present the peptide antigen to the CD8 subpopulation of T lymphocytes. Therefore, the main function of CD8 T lymphocytes is to destroy virus-infected or cancer cells. MHC class II molecules are found on the surface of professional antigen-presenting cells, B lymphocytes, monocytes, and dendritic cells; can be induced on the surface of other cells; present peptide fragments of proteins from pathogens that are taken up and degraded by antigen-presenting cells; and present antigen to the CD4 subpopulation of T lymphocytes. The main functions of CD4 T lymphocytes, therefore, are to help B lymphocytes make antibodies against the invading pathogen and to help monocytes kill ingested pathogens.

IEI are inherited genetic defects affecting the development or function of one or more components of the immune system resulting in an increased susceptibility to infection, immune dysregulation with autoimmunity and/or inflammation, allergic diseases or cancer. There are over 400 different gene defects causing IEI and many more to be discovered.

Defects of adaptive immunity

Adaptive immunity is composed of a humoral component, antibodies secreted by B cells, and a cellular component, activated T cells, which help B cells make antibodies, help phagocytes kill intracellular pathogens, and directly kill virally-infected and cancer cells (cytotoxic T cells) (Murphy and Weaver, 2017). The adaptive immune system is characterized by specificity that is determined by antigen receptors on B cells (Immunoglobulin molecules) and T cells (T cell receptors, TCR); variability, that is determined by the random rearrangement of the genes that encode for the variable region of the antigen receptors; memory, that allows rapid responses at subsequent exposure to a pathogen, and tolerance; that helps prevent inflammatory, autoimmune and allergic diseases.

Immunodeficiencies affecting cellular and humoral immunity

Severe combined immunodeficiency disease

Severe combined immunodeficiency disease (SCID): results from the absence or lack of function of T lymphocytes with or without B lymphocytes and/or Natural Killer (NK) lymphocytes (Notarangelo, 2010; van der Burg and Gennery, 2011). Patients with SCID lack T cell immunity and, in most cases, antibody-mediated immunity. In cases where B lymphocytes are present, the B lymphocytes may be dysfunctional or they may lack T lymphocyte help. The result is a severe immunodeficiency that presents early in life with recurrent bacterial, viral, fungal, and opportunistic infections, chronic diarrhea, and failure to thrive in some cases. Patients are prone to develop disease by attenuated live-viral vaccines, especially BCG given at birth and therefore should not receive any of the live attenuated vaccines. Patients are also susceptible to a fatal reaction from a blood transfusion known as Transfusion graft vs. host (T-GVH) disease (Park et al., 1974). This results from the presence of lymphocytes in the transfused blood which recognize the patient's tissues as foreign and initiate a rejection reaction that is usually fatal if not treated. The reaction starts as a rash but can extend to involve the liver, lung, and/or intestinal tract. Normally, the immune system of the recipient of a blood transfusion will destroy any lymphocyte or other WBC in the donor blood. However, in SCID, the patient has no functioning immune system to destroy the foreign lymphocytes and is thus a target for T-GVH disease. It is therefore very important to irradiate all blood products given to SCID patients, which inhibits the capacity of lymphocytes to mount a GVH reaction. In addition, patients with SCID may have maternal lymphocytes especially T cells (maternal T cell engraftment) that cross the placenta and may result in sufficient numbers of T cells that may delay the diagnosis of SCID but can also result in maternal T cell induced GVH disease, which is rarely fatal. Treatment of SCID requires stem cell transplantation (Dvorak et al., 2013), although some conditions such as adenosine deaminase deficiency (ADA) may be treated with enzyme replacement (Serana et al., 2010) and some SCID patients have been treated successfully by gene therapy such as X-linked SCID and ADA deficiency (Booth et al., 2011; Fischer et al., 2011). However, some of the X-SCID patients treated with gene therapy developed leukemia, which has prompted a revision of the viral vectors used in gene therapy trials.

The severity of the immune deficiency in SCID and the availability of treatment, stem cell transplantation, that has a higher success rate if performed early (Pai et al., 2014), as well as gene therapy or enzyme replacement, has led to the development of newborn screening for SCID (Buckley, 2012; Chase et al., 2011; Chan and Puck, 2005), which has been implemented in several states. The screening method makes use of DNA circles that are formed in new T lymphocytes (naïve T cells) when the TCR genes are rearranged (*T cell Receptor Excision Circles*, TRECs) and can be amplified by quantitative polymerase chain reaction to identify newborns with low or absent T lymphocytes. The identified newborns are then screened for SCID, DiGeorge syndrome [See below] and other T lymphocyte deficiencies (Kwan et al., 2014).

T-B+ SCID

X-linked SCID results from a defect in the gene that encodes the common gamma chain, a molecule that is part of many cytokine receptors including the receptors for interleukin-2 (IL-2), IL-4, IL-7, IL-9, IL-15, and IL-21 (Tangye et al., 2020). IL-7 is necessary for T cell development and IL-15 for NK cell development and therefore, X-SCID is characterized by the absence of T cells and NK cells but the presence of B cells that do not function properly. Similarly, defects in the signaling pathway of these receptors such as JAK-3 kinase results in a similar phenotype but affects boys and girls equally. There are many other gene defects that affect T cell development only (IL-7R alpha chain, members of the CD3 complex and CD45 among others) but nevertheless result in SCID because of the central role of T cells in adaptive immunity (Tangye et al., 2020).

T-B- SCID

Deficiency in enzymes such as adenosine deaminase and purine nucleotide phosphorylase result in the accumulation of metabolites that are toxic to all lymphocytes and usually present with very low or absent numbers of T cells, B cells and NK cells (Table 1). In contrast, defects in the enzymes that mediate recombination of the variable regions of antigen receptors (immunoglobulin in B cells and TCR in T cells) affect the development of T cells and B cells only with normal or elevated numbers of NK cells (Tangye et al., 2020).

A group of T-, B- and NK+ SCID are associated with radiation sensitivity with microcephaly such as in ligase IV deficiency and without microcephaly such as in Artemis deficiency (Tangye et al., 2020).

Table 1 Phenotype and genetic causes of some forms of SCID.

Phenotype	Type of defect	Examples of gene defects
T- B- NK-	Global defect in lymphocytes +/- other hematopoietic cells	Adenosine deaminase Purine nucleotide phosphorylase Reticular dysgenesis (AK2 deficiency) Recombinase activation gene (RAG)-1 RAG-2
T- B- NK+	Defect in antigen receptor recombination	Artemis DNA-PKcs
T- B+ NK-	Defect in cytokine receptor common gamma chain signaling pathway	Common gamma chain (X-SCID) Janus kinase 3 (JAK3)
T- B+ NK+	T cell specific defect	IL-7R α chain CD45 deficiency CD3 $\delta/\epsilon/\zeta$ chain defect
CD8 deficiency	CD8 T cell specific defect	CD8 α chain ZAP-70
CD4 deficiency	CD4 T cell specific defect	MHC class I deficiency MHC class II deficiency

Combined immunodeficiency

X-linked immunodeficiency with normal or elevated IgM (X-linked hyper IgM, X-HIGM): is a rare genetic disorder characterized by markedly decreased or absent serum levels of IgG and IgE immunoglobulins with normal or elevated levels of IgM (Qamar and Fuleihan, 2013). The syndrome was first described in 1961 (Rosen et al., 1961; Burtin, 1961) and since then over 200 cases have been reported worldwide (Levy et al., 1997; Winkelstein et al., 2003; Lee et al., 2005). Affected males are susceptible to recurrent bacterial infections, opportunistic infections with *Pneumocystis jiroveci* and with *Cryptosporidium*, that may be complicated with sclerosing cholangitis and cancer (Hayward et al., 1997). X-HIGM can be differentiated from XLA by the presence of normal numbers of mature B lymphocytes and by the ability to make specific antibodies in response to immunization. However, these antibodies are restricted to the IgM isotype, with a failure to switch to the production of other isotypes (IgG, IgA, and IgE). Some patients are able to synthesize low or normal levels of IgA. In addition, there is a lack of a memory response, which is characterized by a rapid production of larger quantities of antibodies upon re-exposure to a pathogen or vaccine. The lymph nodes, while present, have an abnormal architecture (Facchetti et al., 1995). The underlying defect in X-HIGM appears to be an inability to undergo immunoglobulin isotype switching from IgM/IgD secretion to the production of other immunoglobulin (Ig) isotypes, IgG, IgA, or IgE. In 1993, five independent groups identified the genetic defects in X-HIGM to be in the gene encoding for a protein that is expressed on the surface of activated T lymphocytes and provides the signal B lymphocytes require for isotype switching by binding to CD40 on the surface of B lymphocytes (Allen et al., 1993; Aruffo et al., 1993; DiSanto et al., 1993; Fuleihan et al., 1993; Korthauer et al., 1993). This molecule was therefore named CD40 ligand (CD154). Numerous mutations that disrupt the ability of CD40 ligand to bind to CD40 have been found in X-HIGM. There are autosomal recessive forms of hyper IgM that affect the signaling pathway of CD40 including mutations in CD40 itself (Ferrari et al., 2001), which has a clinical picture similar to X-HIGM.

The defect in X-HIGM is not limited to the lack of T lymphocyte help to B lymphocytes because CD40 has been found on the surface of many other cell types. CD40 ligand on T lymphocytes also provides help to monocytes via CD40 to kill intracellular pathogens, which may be important in clearing infections by opportunistic organisms. Furthermore, interaction of CD40 and its ligand has been found to play many other important roles in the immune response to infection and in the development of immune-mediated diseases (Elgueta et al., 2009).

Treatment of X-HIGM consists of immunoglobulin replacement therapy, PJP prophylaxis, and general precautions to prevent *Cryptosporidium* infection but patients remain susceptible to severe complications including cancer. Stem cell transplantation has been used with success to treat patients with X-HIGM (Ferrua et al., 2019; de la Morena et al., 2017) as well as CD40 deficiency (Mazzolari et al., 2007).

Other combined immunodeficiency diseases include a group of immunodeficiency diseases that are associated with autoimmunity, recurrent infection and hypogammaglobulinemia such as in ICOS & ICOSL deficiency, the latter may also be associated with neutropenia (Tangye et al., 2020).

Autoimmunity and/or immune dysregulation with normal immunoglobulin are caused by a group of genetic defects such as CD8 deficiency in which patients have absent CD8, others are associated with low CD8 such as in ZAP70 (LOF/GOF) and MHC class I deficiency (Tangye et al., 2020). In contrast MHC class II, deficiency, characterized by low CD4 T cell numbers, reduced MHC II expression on lymphocyte, normal or low immunoglobulin, can present in infancy with infections & failure to thrive mimicking SCID, called the bare lymphocyte syndrome (Shrestha et al., 2012). MHC molecules are important for T cell development in the thymus. CD4 T cells develop if they can receive a signal from MHC class II molecules and CD8 T cells from MHC class I molecules (Murphy and Weaver, 2017). In their absence, there is a marked deficiency of the respective T cell subset, but unlike mice, the deficiency is not complete. However, the T cells that do develop do not function properly because there are no molecules to present the peptide antigens necessary for antigen recognition and T cell activation.

Dedicator of cytokinesis 8 (DOCK8) is critical for cytoskeletal organization, and deficiency of DOCK8 impairs dendritic cell transmigration, T cell survival, and NK cell cytotoxicity (McGhee and Chatila, 2010). Deficiency of DOCK 8 is an autosomal recessive disease, characterized by recurrent sino-pulmonary infections, cutaneous viral infections especially Herpes skin infections (Zhang et al., 2009; Randall et al., 2009; Engelhardt et al., 2009). Patients with the disease may have severe eczema, multiple food allergies, elevated IgE and eosinophils. DOCK2 deficiency has recently being reported as a cause of combined immunodeficiency.

Combined immunodeficiencies with associated or syndromic features

Thymic defects with additional congenital anomalies

The DiGeorge anomaly: is a genetic disorder that results in a developmental anomaly affecting several tissues, including the thymus, parathyroid glands, heart, and some structures of the face (McDonald-McGinn and Sullivan, 2011). Patients usually have a congenital defect of the heart, low calcium levels in the blood secondary to low or absent parathyroid hormone, and low numbers of T lymphocytes because of a small or absent thymus. Congenital heart disease is the major life-threatening defect in this disease. Low calcium results in tetany (cramp-like involuntary spasms). The immunodeficiency varies from mild to severe and is related to the number and function of mature T lymphocytes. If patients survive the neonatal period, they become susceptible to recurrent infections, including fungal and opportunistic infections, diarrhea, and failure to thrive as well as autoimmune disease. Patients, especially with milder immunodeficiency, tend to develop improved immune function with age. The anomaly is associated with a deletion in chromosome 22 at 22q11.2 or a mutation in the TBX1 gene located in this region (Tangye et al., 2020). In rare cases, there is complete absence of thymic tissue and T cells, (Complete DiGeorge), which has been treated successfully by thymic transplantation (Markert et al., 2009).

Immunodeficiency with congenital thrombocytopenia

Wiskott-Aldrich syndrome (WAS) is characterized by the triad of eczema, thrombocytopenia with small platelets and a combined immunodeficiency resulting in recurrent sino-pulmonary infections as well as a susceptibility to autoimmunity and/or cancer (Massaad et al., 2013). WAS results from defects in an X-chromosome gene encoding for a protein that is a regulator of the cytoskeleton and termed WAS protein (WASP) (Derry et al., 1994). There is a large variability in the clinical phenotype ranging from thrombocytopenia alone (X-linked thrombocytopenia, XLP) to the full spectrum of the disease. Defects in the gene encoding a WASP-interacting protein (WIP) also results in an immunodeficiency with congenital thrombocytopenia (Lanzi et al., 2012). WAS can be treated by stem cell transplantation (Burroughs et al., 2020) and possibly by gene therapy, which is under investigation currently (Ferrua et al., 2020).

Hyper IgE syndromes

Autosomal dominant mutations in the signaling molecule STAT3 results in the classic Hyper IgE syndrome also known as Job's or Buckley syndrome (Bergerson and Freeman, 2019). Patients have severe eczema, elevated serum IgE levels and are susceptible to Staph infections (cold abscesses) as well as invasive fungal infections, likely due to the failure of differentiation of TH17 T cells. The disease is also associated with non-immunological features include connective tissue, skeletal and vascular abnormalities. Autosomal dominant mutations in the genes encoding for ERBIN and CARD11 as well as autosomal recessive defects in the genes for DOCK8 (see combined immunodeficiency above), IL-6 receptor, IL-6 signal transducer (IL6ST) and phosphoglucosyltransferase 3 (PGM3) also cause an hyper IgE syndrome with susceptibility to infection and variable expression of non-immunologic manifestations (Tangye et al., 2020).

Predominantly antibody deficiencies

Agammaglobulinemia: the prototype antibody deficiency: X-linked agammaglobulinemia (XLA) was the first immunodeficiency to be described. In 1952, Ogden C. Bruton described a young boy with recurrent bacterial infections who had no immunoglobulins in his serum (Bruton, 1952). He also demonstrated that administration of immunoglobulins (plasma) derived from normal individuals resulted in a reduction of the frequency of the patient's bacterial infections. Plasma cells, which secrete immunoglobulins, were found to be lacking in patients with XLA (Good, 1954), and it was later shown that the cellular defect in XLA was the absence of mature B lymphocytes (Geha et al., 1974). These studies on XLA patients discovered that antibodies (immunoglobulins) were secreted by plasma cells, which were derived from B lymphocytes and highlight the role of investigating IEL in our knowledge and understanding of the development and function of the immune system in health and in disease. Affected males develop recurrent bacterial and viral infections early in infancy or childhood; usually after 4–6 months of age, when the protective maternal antibodies that crossed the placenta during the third trimester of pregnancy have decreased (Minegishi et al., 1999). The main finding on physical examination is the absence of tonsils and lymph nodes. Levels of all immunoglobulin isotypes in the serum are markedly decreased if not absent, and, despite repeated immunization, the patients cannot synthesize specific antibodies. Few if any mature B lymphocytes are found in the blood. Although in vitro studies of T lymphocyte number and function are normal, patients

with XLA are prone to develop chronic infections with enteroviruses. Indeed, these patients can contract vaccine-associated paralytic poliomyelitis, for which reason attenuated live-viral vaccines (especially poliomyelitis) should be avoided in patients with XLA. The use of immunoglobulin replacement therapy intravenously or subcutaneously has allowed patients to lead practically normal lives with a marked reduction in the number and severity of infections (Garcia-Lloret et al., 2008).

Immunoglobulins are synthesized by B lymphocytes, which develop in the bone marrow from stem cells that also give rise to other cells found in the blood. B lymphocyte precursors undergo several stages of development before they become mature B lymphocytes, characterized by the presence of surface immunoglobulin molecules capable of recognizing foreign pathogens [See B lymphocytes, Development of]. The defect in XLA affects the development of B lymphocytes such that fewer and fewer B lymphocytes present at each successive stage of development. The gene responsible for XLA was identified in 1993 by two independent groups (Tsukada et al., 1993; Vetrie et al., 1993). Its protein product was found to be a tyrosine kinase, which has been named Btk (for Bruton's tyrosine kinase). Autosomal recessive forms of agammaglobulinemia result from other gene defects that also affect the development of B cells and result in a similar immunodeficiency affecting males and females equally (Conley et al., 2005). Because of the absence of mature B lymphocytes, patients with agammaglobulinemia cannot synthesize immunoglobulin molecules and thus lack the protective role of antibodies. The absence of antibodies in agammaglobulinemia results in a susceptibility to bacterial and viral infections, some of which can be debilitating or fatal and demonstrate the importance of antibodies in immunity (Fig. 1).

Common Variable Immunodeficiency (CVID): is the most common symptomatic primary immunodeficiency disease (Resnick and Cunningham-Rundles, 2012). CVID has its highest incidence in the second and third decades of life. Diagnostic criteria include a low IgG level, low IgA and/or IgM levels and defective specific antibody synthesis in an adult or child, older than 2 years of age at the time of diagnosis, with recurrent infections and other causes of primary immunodeficiency ruled out. CVID is associated with the development of autoimmune disease particularly affecting cells of the blood such as platelets and red blood cells, and the development of granulomatous disease especially in the lung and bronchiectasis. Some CVID patients have low immunoglobulin levels and autoimmune disease without a history of recurrent infections. Several gene defects affecting B lymphocyte function and survival have been identified, the genetic causes of CVID in most patients have yet to be discovered. Treatment of CVID includes antibody replacement with intravenous or subcutaneous immunoglobulin as well as treatment of any complications that are present at the time of diagnosis or that develop over time.

Hyper IgM syndrome with predominantly antibody deficiency: Defects in the genes that encode for the enzymes important for immunoglobulin isotype switching, activation-induced cytidine deaminase (AID) (Revy et al., 2000) and uracil N-glycosylase (UNG) (Imai et al., 2003), which lead to a HIGM clinical picture that is characterized by an antibody deficiency and lymph node enlargement without a susceptibility to opportunistic infections or cancer because these enzymes are only found in B cells and do not affect T cell function. AID and UNG also mediated somatic hypermutation, a mechanism by which B lymphocytes mutate the variable region to produce antibodies with higher affinity, which is also defective in HIGM patients (Fig. 2).

Selective IgA deficiency: is the most common primary immunodeficiency affecting as many as 1:600 individuals but most patients have few infections or complications (Wang and Hammarstrom, 2012). The prevalence of IgA deficiency, defined as IgA level < 10 mg/dl, varies among different ethnic groups. Recurrent infections, bronchiectasis and autoimmune diseases occur in some patients and may be related to association with IgG subclass deficiency, poor specific antibody responses or low class-switched memory B cells. Autoimmune diseases include autoimmune thyroid diseases, type 1 diabetes mellitus, systemic lupus erythematosus, juvenile arthritis and celiac disease. The genetic cause of IgA deficiency remains elusive but appears to be associated with genes within the Major Histocompatibility Complex (MHC) area on chromosome 6 as well as non-MHC genes. Treatment with IgG replacement therapy is usually not indicated unless there is a demonstrated specific antibody deficiency associated with severe or recurrent infections that are not preventable by antibiotic prophylaxis. Exposure of patients with complete absence of IgA to blood products including IgG replacement products, which contain variable amounts of IgA, may elicit an anti-IgA antibody response that

Fig. 1 Antibody deficiency results in a susceptibility to infection, which may be severe in agammaglobulinemia and CVID or more limited susceptibility in IgA deficiency and specific antibody deficiency.

Fig. 2 Schematic representation of interaction between an activated CD4 T lymphocyte and a B lymphocyte. CD40 ligand (CD40L) binds to CD40 and activates immunoglobulin isotype switching from IgM to IgG, IgA or IgE as well as somatic hypermutation mediated by AID and UNG. In addition, CD40 stimulates expression of molecules that provide co-stimulation to the CD4 T cell. Mutations in CD40 ligand cause X-HIGM, whereas mutations in CD40, AID or UNG result in autosomal recessive HIGM. Susceptibility to opportunistic infections occurs with proximal defects (CD40 ligand and CD40) whereas the distal defects (AID and UNG) are associated with lymphoid hyperplasia.

can result in an allergic reaction upon subsequent transfusions/infusion (Rachid and Bonilla, 2012). While this has been documented, it is not very common and should not delay the lifesaving administration of blood products especially if it is the patient's first infusion. The patient can be tested subsequently for anti-IgA antibodies prior to receiving further blood products.

Specific antibody deficiency: is an immunodeficiency defined as an inability to synthesize antibody to specific antigens usually the polysaccharide antigens of encapsulated bacteria with normal serum levels of immunoglobulins and normal numbers of B cells (Leiva et al., 2013). Patients are susceptible to recurrent infections and may be treated with prophylactic antibiotics or IgG replacement if they have severe infections or if they fail antibiotic prophylaxis. Specific antibody deficiency can be associated with other conditions including IgG subclass deficiency, IgA deficiency, Wiskott-Aldrich syndrome or DiGeorge syndrome [See below] among others. The underlying cause of this immunodeficiency has not been determined yet.

Diseases of immune dysregulation

The association of autoimmunity with several immunodeficiency diseases such as selective IgA deficiency, CVID and DiGeorge Syndrome hinted to the presence of immune dysregulation as a result of a defect of immunity or the co-inheritance of autoimmune disease susceptibility with the immune deficiency (Cunningham-Rundles, 2011). However, the discovery of the genetic cause of Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) highlighted the role of regulatory T cells in immune homeostasis and opened up the field of immune dysregulation as a defect in immunity even if not associated with susceptibility to infection (Bennett et al., 2001; Chatila et al., 2000). IPEX results from defects in the gene encoding for FoxP3, a transcription factor necessary for the generation of thymic regulatory T cells. The disease is associated with both autoimmune as well as allergic disease, namely food allergy, emphasizing the role of regulatory T cells in controlling or preventing autoimmunity as well as food allergy and likely other allergic diseases. Other defects in regulatory T cell function such as in IL-10 or its receptor, CD25 deficiency, CTLA-4 haploinsufficiency or autosomal recessive LRBA deficiency lead to immune dysregulation including autoimmunity, enteropathy and inflammatory bowel disease (Tangye et al., 2020).

Predisposition to autoimmunity is probably best exemplified by APECED resulting from a defect in the AIRE gene that is responsible for expression of self-proteins, particularly proteins expressed in endocrine organs, in the thymus, where negative selection occurs (Tangye et al., 2020). AIRE also has a role in regulatory T cell development. Autoimmunity to IL-17 and IL-22 appears to underlie the association of chronic mucocutaneous candidiasis in APECED (Puel et al., 2010; Kisand et al., 2010).

Autoimmunity with lymphoproliferation results from defects in the FAS apoptotic pathway leading to Autoimmune Lymphoproliferative Syndrome (ALPS) with defects in Fas, Fas ligand and downstream Caspases 8 and 10 (Tangye et al., 2020). This condition was first reported by Canale and Smith (Canale and Smith, 1967) and later found to be the same disease as ALPS (Rieux-Laucat et al., 1995; Fisher et al., 1995), when Fas mutations were demonstrated in patients described by Canale and Smith (Drappa et al., 1996).

Other disease of immune dysregulation result from defects in NK cell and cytolytic T cell function such as defects in perforin and UNC13D that lead to familial hemophagocytic lymphohistiocytosis (FHL) or LYST, Rab27a, and AP3B1 and AP3D1 that lead to FHL with hypopigmentation, Chediak-Higashi syndrome, Griscelli syndrome type 2, and Hermansky-Pudlak syndrome types 2 and 10, respectively (Tangye et al., 2020).

Susceptibility to EBV infection and lymphoproliferation also results from defects in NK cell function as well as NKT cell development (Nichols et al., 2005) characterized by X-linked lymphoproliferative disease (XLP) resulting from defects in the SH2D1A gene (Sayos et al., 1998; Nichols et al., 1998). Defects in X-linked inhibitor of apoptosis (XIAP) also results in a susceptibility to EBV and lymphoproliferation (Rigaud et al., 2006) as well as recurrent HLH (Marsh et al., 2010) and inflammatory bowel disease (Kelsen et al., 2015).

Defects of innate immunity

The innate immune system is important for the initial recognition of a foreign pathogen, mounting an immediate response that often clears the invading pathogen, and if not, initiates an inflammatory response that controls the infection while activating the adaptive immune system (antibodies made by B cells and activated T cells that can kill virally infected cells) to clear the infection (Medzhitov and Janeway, 1997). Defects in any of the components of the innate immune system can lead to frequent or severe infections (Rosenzweig and Holland, 2011). In some cases, while there is an initial serious and life-threatening infection, recurrent infections do not develop because the adaptive immune system with immunological memory is able to control subsequent infections (Alcais et al., 2010).

Congenital defects of phagocyte number or function

The phagocytic system plays a very important role in killing pathogens early in an infection. Phagocytes include neutrophils, eosinophils, and basophils. Neutrophils are the most abundant of the phagocytic cells [See Neutrophils]. Their main function is to ingest (phagocytose) and kill pathogens. Defects in the number or function of neutrophils result in a susceptibility to recurrent bacterial and fungal infections (Rosenzweig and Holland, 2011). Patients suffer from soft tissue inflammation and abscesses. They have an enhanced susceptibility to infection by some bacteria (*Staphylococcus aureus*, *Pseudomonas*, and *Serratia*) and by some fungi (*Aspergillus* and *Candida*). Defects in neutrophil numbers are mostly secondary; however, congenital neutropenia does occur, leaving affected individuals susceptible to recurrent infections. Defects in neutrophil function result from a variety of genetic defects:

Leukocyte Adhesion Deficiency: results from defects in molecules found on the surface of neutrophils (integrins), which allow neutrophils to bind (adhere) to the cells lining the blood vessels (vascular endothelium). Adherence to vascular endothelium is the first step in the process of neutrophil migration to the site of infection (Rosenzweig and Holland, 2011). As a result of this deficiency, neutrophils remain in the blood vessels where they are found in higher numbers than normal. Leukocyte adhesion-deficient neutrophils cannot reach the sites of infection, resulting in the absence of pus. One of the earliest signs of a leukocyte adhesion deficiency is delayed separation of the umbilical cord beyond 2 weeks especially if it is associated with an infection around the umbilical cord (Omphalitis).

Chronic Granulomatous Disease (CGD): results from an inability to kill ingested bacteria. Killing of bacteria by neutrophils involves a burst of respiratory activity to generate superoxide (Rosenzweig and Holland, 2011). Defects in any of the enzymes involved in the respiratory burst can lead to a defect in intracellular killing by neutrophils. Five enzyme defects have been described to date and are inherited as autosomal recessive disorders (p22-phox, p40-phox, p47-phox, and p67-phox), except for the most common gene defect in CGD (gp91-phox), which is located on the X chromosome. The diagnosis of CGD is made by a test known as the nitroblue tetrazolium dye (NBT) test, where a soluble yellow dye becomes an insoluble blue dye in activated neutrophils, and more recently, by a flow cytometry-based dihydrorhodamine 123 (DHR) assay, which is a more sensitive test converting DHR into a brightly fluorescing rhodamine. Female carriers of the X-linked form of this disease will demonstrate NBT dye reduction in only a subset (average 50%) of their neutrophils, the subset carrying the normal gene, or will show two peaks of fluorescence in the DHR assay (a normal and an abnormal peak). Although no specific therapy exists, patients have been found to benefit from the regular administration of interferon- γ (IFN- γ) (1991), as well as from the administration of prophylactic antibiotics and antifungals (Kang et al., 2011). Stem cell transplantation offers a potential cure (Cole et al., 2013), is possible when the patient has a suitable related or unrelated donor and is recommended in patients with absent or very low oxidative burst (Kuhns et al., 2010).

Other Phagocytic Deficiencies: result from defects in other enzymes such as severe deficiency of (G6PD) glucose-6-phosphate dehydrogenase (Tangye et al., 2020) or deficiency in myeloperoxidase (Pahwa et al., 2021).

Defects in intrinsic and innate immunity

Mendelian susceptibility to mycobacterial disease (MSMD) results from defects in genes involved in the production of interferon gamma (IFN- γ) or in the IFN- γ signaling pathway including IL-12 and its receptor, IFN- γ receptors, STAT1, Macrophage gp91phox, IRF8, Tyk2, ROR γ t, and JAK1 (Tangye et al., 2020; Rosain et al., 2019). Defects that affect IFN- γ production can benefit from treatment with IFN- γ , however, defects of the IFN- γ receptor and its downstream signaling pathway are resistant to addition of IFN- γ and may require stem cell transplantation.

TLR signaling pathway deficiency with bacterial susceptibility: Toll-like receptors (TLR) are pattern-recognition receptors found on the surface of cells or inside cells and recognize classes of pathogens including gram positive bacteria, gram negative bacteria, fungi, DNA or RNA viruses (Janeway and Medzhitov, 2002). Most TLR signal via a similar pathway to activate an inflammatory reaction that helps in the control of the invading pathogen and in the activation of the adaptive immune system to clear the infection. Genetic defects in several of the TLR or their signaling pathway have been associated with severe or recurrent infections, each TLR pathway defect is associated with a narrow window of susceptibility (Picard et al., 2011). Defects in TLR or their respective signaling pathways have been associated with invasive Staphylococcal and Streptococcal infections with minimal fever and inflammation (IRAK-4, MyD88 defects) or herpes virus encephalitis (TLR3, UNC93B and TRAF-3) among others (Tangye et al., 2020).

Autoinflammatory disorders

Type 1 interferonopathies result from gene defects that affect the regulation of type I interferons resulting in inflammatory conditions resembling rheumatologic diseases such as systemic lupus erythematosus and vasculitis (Rodero and Crow, 2016). Affected genes include *Trex1*, *RNASEH2B*, *C* and *A*, *SAMHD1* and other genes causing Aicardi-Goutieres syndrome, *TMEM173* causing STING-associated vasculopathy, infantile-onset (SAVI), *ADA2* and others.

Defects affecting the inflammasome lead to periodic fever syndromes exemplified by Familial Mediterranean Fever caused by defects in the *MEFV* gene, Hyper IgD syndrome caused by defects in the *MVK* gene, Muckle-Wells syndrome, Familial cold autoinflammatory syndrome and neonatal onset multisystem inflammatory disease (NOMID) caused by defects in the *NLRP3* gene, *PLCγ2*-associated antibody deficiency and immune dysregulations (PLAID) caused by mutations in the *PLCG2* gene and other familial cold autoinflammatory syndromes (Tangye et al., 2020).

Non-inflammasome-related conditions include a variety of clinical phenotypes including recurrent fever, arthritis, myositis, Panniculitis, and chronic recurrent multifocal osteomyelitis (Tangye et al., 2020). Diseases include TNF receptor-associated periodic syndrome (TRAPS) caused by defects in the *TNFRSF1A* gene, Majeed syndrome caused by defects in the *LPIN2* gene, deficiency of the interleukin 1 receptor antagonist (DIRA) caused by defects in the *IL1RN* gene and others.

Deficiency of the complement system

Deficiency of proteins: The complement system involves a large number of serum proteins (at least 30) that participate in the killing of pathogens (Rosenzweig and Holland, 2011). Nine of these proteins are numbered C1-C9. Activation of the complement system results in the generation of a complex formed by the proteins C5-C9, which can destroy bacteria. Three mechanisms activate the complement system: the classical pathway via antibodies which utilizes the early components, C1, C2 and C4 proteins, the alternative pathway which activates C3 spontaneously and the lectin pathway, which is activated by mannose binding lectin and ficolins that bind to carbohydrate molecules on pathogens. All three pathways lead to activation of C3 and then the formation of the membrane attack complex C5-C9. Therefore, complement proteins can directly kill some bacteria or can help antibodies to kill bacteria. Deficiency of any of the early components leads to a decreased efficiency of antibody function and, therefore, to an enhanced susceptibility to infections. In addition, the early complement proteins appear to play a role in the clearing of antibody/antigen complexes. Therefore, patients deficient in one of the early complement proteins are also susceptible to diseases generated by immune complexes. Deficiency of any of the late components, C3, C5-C8 proteins, results in an enhanced susceptibility to *Neisseria meningitidis* infections. Deficiency of C9 does not result in as severe an immunodeficiency because the C5-C8 complex has some antibacterial activity.

Bone marrow failure syndromes

Inherited diseases that lead to bone marrow failure can cause immunodeficiency by affecting the development of immune cells including neutrophils, monocytes, and various lymphocyte subsets. Examples include gene defects causing Fanconi anemia and Dyskeratosis congenita (Tangye et al., 2020).

Phenocopies of inborn errors of immunity

Acquired immune deficiency or dysregulation resembling inherited diseases in children can result in adults from somatic mutations in gene leading to autoimmune lymphoproliferative syndromes, cryopyrinopathies and hypereosinophilia (Tangye et al., 2020). In addition, the development of autoimmunity directed against cytokines and their receptors can result in disease mimicking the inherited childhood diseases (Browne and Holland, 2010) including chronic mucocutaneous candidiasis from autoantibodies to IL-17 and its receptor, susceptibility to mycobacteria with autoantibodies to IFN- γ , recurrent skin infections with autoantibodies to IL-6, susceptibility to severe viral infections including SARS-CoV2 with autoantibodies to type I interferons (Bastard et al., 2020).

Concluding remarks

There are many other primary immunodeficiency diseases and diseases of immune dysregulation that affect the innate and/or adaptive immune system with susceptibility to severe infections, including opportunistic infections, cancer, autoimmune, inflammatory or allergic disease (Tangye et al., 2020). This article describes only a few of the known genetic immune deficiency diseases within each category of immune deficiency or dysregulation that illustrate how a single gene defect can have such a profound effect on the immune system. Studying patients with these diseases can lead to important findings on how the immune system works and allows for the development of novel therapeutic approaches for immunodeficiency diseases, cancer, allergic diseases, autoimmune diseases, inflammatory diseases including autoinflammatory defects in the innate immune system. The immune system is at the center of health and disease and primary immunodeficiency diseases are experiments of nature that teach us about the immune system and how its different components work to fight infection or cause disease.

Introduction

The key cells of the adaptive immune response are T-lymphocytes and B-lymphocytes. Defects in T-lymphocytes alone or both T- and B-lymphocytes give rise to combined immunodeficiency, as B-lymphocyte function requires T-lymphocyte interaction. Combined T- and B-lymphocyte deficiencies are the most common immunodeficiencies after antibody deficiencies and in the 2019 International Union of Immunological Societies classification, are defined in [Tables 1 and 2](#) of the latest publication ([Tangye et al., 2020](#)).

Severe combined immunodeficiencies

Severe combined immunodeficiencies (SCID) are the most profound combined immunodeficiencies and have been described as a pediatric emergency. They comprise a group of inherited disorders whose hallmark is deficient T-lymphocyte differentiation, due to genetic defects causing disruption of lymphocyte development ([Fischer et al., 2015](#); [Tangye et al., 2020](#)). Contingent on the genetic

defect, B-lymphocytes may be affected: they may be absent, or intrinsically non-functioning. However, if B-lymphocytes are present and intrinsically functional, the absence of CD4⁺ T-lymphocytes in SCID prevents B-lymphocyte activation and generation of normal antibody responses producing a combined cellular and humoral immune deficit. Natural killer (NK) cells may be present or absent. Almost 20 different genetic causes of SCID are now described (Table 1), but clinical presentation is similar regardless of genotype.

Clinical presentation

First clinical presentation of an infant is within the first few months of life. Without curative treatment, most patients do not survive beyond the first 12–18 months. Infection is the most common manifestation—persistent respiratory tract infection is frequently encountered, with a failure to clear viruses accompanied by persistent bronchiolitic-like signs including tachypnea, nasal flaring, subcostal and intercostal recession, with widespread crepitations and rales, and cyanosis. Persistent viral-associated diarrhea with accompanying growth failure is also common, and vaccine-strain viruses (e.g., rotavirus) may be detected if the infant has been vaccinated. Infants with SCID are often initially well and growing normally, but fall away from the growth centile when infection occurs, because of malabsorption secondary to intestinal villous atrophy, which in severe cases causes malnutrition (van der Burg and Gennery, 2011). Progressive respiratory symptoms accompanied by an oxygen requirement and radiological evidence of

Fig. 1 Chest radiograph from an infant with severe combined immunodeficiency showing hyperinflated lungs with mid-line pleural borders of the upper lobes visible in the absence of a thymic shadow, and interstitial pneumonitis secondary to *Pneumocystis jirovecii* pneumonia and parainfluenzae type 3 infection. Courtesy of the Bubble Foundation, UK.

interstitial pneumonitis and hyperinflation, suggests *Pneumocystis jirovecii* infection (Fig. 1) (Berrington et al., 2000). There may be oral or perineal candidiasis and other superficial infections. Frequently, patients are infected with multiple organisms. Immunization with the live attenuated Bacillus Calmette-Guérin (BCG) vaccine can result in disseminated BCG infection, affecting bones, marrow, liver, brain and respiratory tract (Marciano et al., 2014).

Whilst most genetic forms of SCID present with similar clinical features, there are some gene defects that warrant specific mention.

Adenosine deaminase deficiency

Adenosine deaminase (ADA)-deficient SCID, caused by loss of function mutations in the *ADA* gene, is a systemic metabolic defect. Adenosine deaminase is an indispensable purine salvage pathway enzyme, in which deficiency causes one of the more common autosomal recessive SCID syndromes, accounting for approximately 10–15% of cases in outbred populations (Gaspar, 2010). Adenosine deaminase is essential for the irreversible deamination of adenosine to inosine and 2′deoxyadenosine to 2′deoxyinosine and absent or impaired function of ADA causes intracellular and extracellular accumulation of these toxic substrates, and deoxyadenosine triphosphate (dATP). ADA-deficient SCID is typified by severe pan-lymphocytopenia affecting T- and B-lymphocytes and NK cells. Whilst the infectious complications encountered by patients are the same as for other genetic causes of SCID, the systemic distribution of the enzyme is manifest in non-immunological features, including neurodevelopmental deficits (Rogers et al., 2001) sensorineural deafness (Albuquerque and Gaspar, 2004) and skeletal abnormalities, particularly of the scapulae and ribs (Fig. 2) (Sauer et al., 2009; Manson et al., 2013).

Fig. 2 Chest radiograph from an infant with adenosine deaminase-deficient severe combined immunodeficiency showing abnormal squaring of the scapulae and cupping deformities at the ends of the ribs. Courtesy of the Bubble Foundation, UK.

A particular feature is the presence of early-onset severe respiratory symptoms caused by direct toxicity of adenosine metabolites on lung tissue, confirmed in experimental models: *Ada*^(-/-) mice demonstrate severe pulmonary inflammation, with accompanying accumulation of activated macrophages and eosinophils. The resultant inflammation initiates airway remodeling, which is reversible if treated early with polyethylene-glycosylated ADA enzyme replacement therapy (Blackburn and Kellems, 2005). Prolonged exposure of lung tissue to high adenosine concentrations due to inadequate treatment with low dose enzyme replacement therapy causes pulmonary fibrosis, although the changes can be reversed by decreasing pulmonary adenosine levels (Chunn et al., 2005). ADA-deficient patients exhibit similar non-infectious pulmonary manifestations including pneumonitis and pulmonary alveolar proteinosis, which are described more frequently in this group than in other genetic forms of SCID (Booth et al., 2012). Pulmonary alveolar proteinosis in patients with ADA-deficient SCID resolves upon commencing treatment with polyethylene-glycosylated ADA (Grunebaum et al., 2012). However, co-existence of adenosine-induced pulmonary toxicity and respiratory infection is common, and chest radiography does not differentiate the pathogenesis—therefore, patients with ADA-deficient SCID who exhibit pulmonary symptoms should receive both appropriate anti-microbial treatment and polyethylene-glycosylated ADA enzyme replacement therapy.

Reticular dysgenesis

Patients with loss-of-function mutations in *AK2* that encodes adenylate kinase 2 have a particular form of SCID characterized by agranulocytosis in addition to pan-lymphocytopenia with absence of T- and B-lymphocytes and NK cells. Classically, patients are born pre-term, or are small for gestational age. There is associated sensorineural deafness. Whilst the majority of infants with SCID present in the first few months of life, the agranulocytosis associated with *AK2* deficiency confers a severe phenotype and patients develop severe symptoms in the first few days or weeks of life. Circulating lymphocytes and granulocytes are generally absent, and the agranulocytosis does not respond to G-CSF. Other hematological indices may be low, including hemoglobin or thrombocytes. An examination of bone marrow may show hypoplasia or hyperplasia. The most common presentation is invasive bacterial infection, usually bacterial sepsis, with respiratory features. Omphalitis is frequently co-existent. Implicated bacteria include *S. aureus*, streptococcal commensal species, *K. pneumonia*, and *E. coli*. Candida sepsis is also described (Hoenig et al., 2017).

Omenn syndrome and atypical SCID

Omenn syndrome is a form of SCID with a characteristic clinical and immunological phenotype. Patients present with an extensive, thickened dermatosis, which is often scaling with erythematous exfoliation, and protein-losing erythroderma, which presents a 'leathery' consistency (Fig. 3). Alopecia, often including eyebrows and eyelashes, develops as the rash evolves. The rash may be present at birth or shortly afterwards, or evolve over the first few weeks of life. There is an associated lymphadenopathy, particularly of the axillary and inguinal nodes. Hepatosplenomegaly is frequently present (Omenn, 1965). The immunophenotype is

Fig. 3 Infant with Omenn syndrome, demonstrating thickened, scaling erythematous exfoliation with alopecia, including eyebrows and eyelashes. Courtesy of the Bubble Foundation, UK.

characteristic, and quite different to classic SCID. A T-lymphocytosis with a highly activated phenotype is found, dominated by a restricted oligoclonal expansion of a few autologous TCRV β families with absence of other families (Harville et al., 1997; de Saint-Basile et al., 1991). Markers of thymopoiesis, such as CD4⁺ CD45RA⁺ CD31⁺ T-lymphocytes, or T-lymphocytes bearing T-lymphocyte Receptor Excision Circles (TRECs), which are episomal DNA formed during T-lymphocyte receptor re-arrangement, representative of a recent thymic emigrant and absent in SCID, are absent. B-lymphocytes are usually absent, and NK cells are generally present in normal numbers. T-lymphocytes fail to proliferate in response to stimulation with phytohemagglutinin. Although serum immunoglobulins IgM, IgA and IgG are absent, with absence of vaccine antigen responses, the serum IgE is usually raised, with an associated eosinophilia.

An important distinction between Omenn syndrome and classical SCID is the presence of intense auto-inflammation. Inflammatory pneumonitis, enteritis, hepatitis may be present (Altmann et al., 2018), usually with coexisting infection with conventional or opportunistic pathogens. The clinico-immunophenotype is similar to that found in patients who have classical SCID with materno-fetal engraftment with graft-versus host disease (Wahn et al., 1991), or classical SCID and blood transfusion-associated graft-versus host disease (Sebnem Kilic et al., 2010), and can be distinguished by determining the origin of T-lymphocytes by molecular techniques (Table 2).

Infants with a clinical diagnosis of classical SCID and mutations in the genes listed in Table 1 demonstrate absent circulating T-lymphocytes. However, those with 'atypical SCID' have normal or elevated T-lymphocyte numbers, and harbor hypomorphic mutations in SCID-causing genes, which permit residual T-lymphocyte development, and most commonly present with severe recurrent pneumonia, rarely due to opportunistic micro-organisms such as *Pneumocystis jirovecii* (Felgentreff et al., 2011).

Other presentations of SCID

Infection is the most common presentation in patients with SCID, particularly of the respiratory or gastrointestinal tract, but other rare presentations are described (Table 3). Very rarely, polymorphous lymphoproliferative lesions, resembling B-lymphocyte lineage lymphomas, have been described, sometimes associated with Epstein-Barr viral infection (Slatter et al., 2011).

Hemophagocytic lymphohistiocytosis, is a life-threatening hyperinflammatory syndrome, more usually linked to defects in genes of the cytotoxic granule-mediated cell death pathway. It has been described in patients with SCID, sometimes in association with engraftment of maternal T-lymphocytes (Bode et al., 2015).

Management

Accurate identification of pathogens is crucial for effective anti-microbial treatment. Nasopharyngeal secretions may yield viruses causing infection of the lower respiratory tract, such as respiratory syncytial virus, but isolates from these samples may indicate upper respiratory tract colonization or infection only (e.g. rhinovirus), and so broncho-alveolar lavage is recommended in these patients—non-bronchoscopic examination is adequate for most patients, but directed fiber-optic bronchoscopy, should be employed in patients with isolated lesions identified on chest imaging (Slatter et al., 2007). Lung biopsy should be considered in symptomatic patients if no pathogen is identified by other means (Hughes, 1991). More than one pathogen may co-exist in these patients (Berrington et al., 2000). Appropriate microbial therapy should be directed at the specific pathogen. Viral infection is difficult to treat and without restoration of T-lymphocyte function, viral clearance will not be achieved (Crooks et al., 2000), although some control may be gained with antiviral agents. In severe cases, donor or third party adenovirus- or cytomegalovirus-specific cytotoxic T-lymphocytes may be administered (Keller et al., 2016) but an intense inflammatory pneumonitis may result and so co-administration of corticosteroids is recommended. Palivizumab, an anti-respiratory syncytial virus monoclonal antibody prevents respiratory syncytial virus infection in high-risk infants, and should be administered to infants with SCID who present during the winter months. The role of palivizumab in treating infants with established lower respiratory tract respiratory syncytial virus infection is less clear—it appears safe to give (Boeckh et al., 2001), but efficacy has yet to be demonstrated (Chávez-Bueno et al., 2007). All infants with SCID should receive immunoglobulin replacement therapy until B-lymphocyte function is restored.

Respiratory impairment confers a significant adverse outcome following hematopoietic stem cell transplantation (Gennery et al., 2010), especially in infants with active infection at time of transplantation (Pai et al., 2014) and the physical condition of infants should be optimized prior to the transplant procedure. Early diagnosis of SCID before infection has occurred gives the best outcomes (Brown et al., 2011), which is why newborn screening for SCID is being introduced in increasing numbers of countries (Kwan et al., 2014).

Table 3 Presentations of severe combined immunodeficiency.

Common Presentations	Rare Presentations
Respiratory infection	Bacterial septicemia
Gastrointestinal infection	Disseminated BCG infection
Candidiasis	Materno-fetal graft-versus-host disease
<i>Pneumocystis jirovecii</i> pneumonitis	Hemophagocytosis
Failure to thrive	Autoimmune cytopenias
	Lymphoid malignancy

Combined immunodeficiencies

Background

Patients with combined immunodeficiency (CID) often present with recurrent respiratory and gastrointestinal tract infections, caused by a wide range of pathogens. Clinical presentation shares features with those of patients with atypical SCID due to residual T-lymphocyte function, although patients with CID usually have a less severe presentation with a later age of onset (>1 year of age). Because of impaired T-lymphocyte function, viral infections can be particularly severe, but depending on the specific immunodeficiency, many different infectious agents are described. Autoimmune manifestations are also common, and in some diseases, lymphoproliferation and lymphoid malignancy is well described. The latest International Union of Immunology Societies classification lists 39 different genes associated with non-syndromic CID (Tangye et al., 2020).

Immunoglobulin class switch recombination deficiencies affecting CD40-CD40L (CD40LG deficiency, CD40 deficiency)

Different genetic defects are described that interrupt the capacity of B-lymphocytes to switch from producing IgM immunoglobulin, to immunoglobulin isotypes with alternative constant regions (IgA, IgE, IgG). Defects are either extrinsic to the B-lymphocyte signaling pathway, or impact the intrinsic B-lymphocyte switch pathway (Table 4). Accurate identification of the defect enables the management approach to be appropriately targeted, according to the specific gene involved (Durandy et al., 2013). CD40 ligand (CD40L) deficiency [X-linked hyper-IgM syndrome type 1], is the most common immunoglobulin isotype class switch defect. It is a rare X-linked primary immunodeficiency caused by mutations in *CD40LG*, on chromosome Xq26.3-Xq27.1, and encodes the transmembrane CD40L glycoprotein (CD154), which is expressed on the surface of activated CD4 T-lymphocytes. Mutations in *CD40LG* alter co-stimulatory T-lymphocyte function, impairing B-lymphocyte isotype switching and dendritic cell signaling, and resulting in increased susceptibility to intracellular and bacterial pathogens. Patients commonly present in infancy or early childhood with recurrent upper and lower respiratory tract infections, including *Pneumocystis jirovecii* interstitial pneumonia (Levy et al., 1997). Cryptosporidium infection is a common cause of acute or chronic diarrhea, and is not cleared. Chronic inflammation may lead to severe biliary tract disease, including sclerosing cholangitis, cirrhosis, and rarely cholangiocarcinoma, hepatocellular carcinoma, and adenocarcinoma (Hayward et al., 1997). Infrequently, infection of the central nervous system, particularly enteroviral meningoencephalitis, or JC virus progressive multifocal leukoencephalopathy, cause progressive neurodegeneration (Cunningham et al., 1999; Aschermann et al., 2007).

Although long-term survival with conservative therapy of immunoglobulin replacement and cryptosporidial prophylaxis has been historically poor, with 20–50% survival to the third decade (Levy et al., 1997; Toniati et al., 2008), recent data demonstrate an improved median survival from diagnosis of 25 years in 109 patients reported with CD40L deficiency (de la Morena et al., 2016). Hematopoietic stem cell transplantation is curative. A multi-center study of 130 patients reported 80% overall survival after transplantation. Better outcomes were associated with transplantation before 10 years of age, or transplantation early after diagnosis. Use of myeloablative conditioning regimens conferred higher overall and disease-free survival, whilst reduced intensity and non-myeloablative conditioning was associated with poor donor cell engraftment (Ferrua et al., 2019). Transplant survivors experienced significantly better well-being, as measured by using Karnofsky/Lansky scales, than those not transplanted (de la Morena et al., 2016).

Mutations in the *CD40* gene, the receptor for CD40L, mimic the phenotype of CD40L deficiency, although inheritance is autosomal recessive, and it is much less common. Expression of CD40 on monocytes and B-lymphocytes is absent or where present, the CD40 protein function is absent or impaired, whereas expression of CD40L is normal. Clinical features overlap those of CD40L deficiency and include bacterial sino-pulmonary infection due to antibody deficiency, as well as infection with opportunistic micro-organisms such as *Pneumocystis jirovecii*. Severe bronchiectasis can develop (Ferrari et al., 2001; Lougaris et al., 2005). Hepatic

Table 4 Immunodeficiencies associated with raised IgM.

Disease	Genetic Defect	Affected cell type	Inheritance

IL21R Deficiency	<i>IL21R</i>	T-lymphocytes, B-lymphocytes, NK cells	AR

disease associated with cryptosporidial infection is reported (Kutukculer et al., 2003). Treatment is the same as for patients with CD40L deficiency—immunoglobulin replacement and antibiotic prophylaxis to prevent *Pneumocystis jirovecii* and *Cryptosporidium* infection. Hematopoietic stem cell transplantation is curative (Al-Saud et al., 2019a).

ICOS and ICOSL deficiency

The inducible T cell co-stimulator (ICOS) belongs to the CD28/CTLA4 family of proteins, and is expressed on activated CD4 T-lymphocytes; signaling through ICOS is induced by interaction with ICOS ligand which is highly expressed on B-lymphocytes, and dendritic cells and weakly present on T-lymphocytes. Signaling through ICOS has wide-ranging effects on the adaptive immune response and is important for augmenting T-lymphocyte proliferation, cell surface molecule expression and cytokine secretion, as well as T-B-lymphocyte co-activation, CD40-CD40L mediated Ig class switch recombination, and development of Th1 and Th2 immune responses. ICOS signaling also has important roles in regulating generation of Th17 cells, and differentiation of FoxP3 regulatory T-lymphocytes. The first descriptions of patients with ICOS deficiency were from cohorts of patients with common variable immunodeficiency, with clinical features including recurrent bacterial infections of the respiratory and gastrointestinal tracts but no other CVID features such as splenomegaly, autoimmunity or granulomas. (Grimbacher et al., 2003; Salzer et al., 2004). ICOS deficiency is listed as a combined immunodeficiency in the IUIS classification and the phenotype expanded, although only 22 patients have been described to date (Takahashi et al., 2009; Robertson et al., 2015; Schepp et al., 2017; Abolhassani et al., 2020). Frequent clinical features include respiratory infections, severe viral infections and enteropathy, but less common presentations are described with autoimmunity, lymphoproliferation and malignancy. Only one patient has been described with ICOSL deficiency (Roussel et al., 2018). The patient had respiratory infections, widespread human papillomavirus warts and oro-labial HSV infections. Hypogammaglobulinemia is described in all patients to date, most with vaccine antigen specific antibody deficiency. Pan-lymphocytopenia is described but not invariable. All have had reduced class-switched memory B-lymphocytes and reduced follicular CD4⁺ T-lymphocytes. Treatment is with antimicrobial prophylaxis (including *Pneumocystis* prophylaxis) and immunoglobulin replacement. Hematopoietic stem cell transplantation has been successfully offered in some patients.

CD3 γ chain deficiency

The CD3 molecule is an essential part of the CD3/T-lymphocyte receptor complex, and is critical for T-lymphocyte maturation. The CD3 molecule itself is composed of a single δ chain and γ chain and two ϵ chains. Defects in CD3 δ and CD3 ϵ confer a SCID phenotype. CD3 γ chain-deficient mice demonstrate a similar phenotype to that of humans with CD3 δ - or CD3 ϵ -deficiency. Although there are few patients described with CD3 γ chain deficiency, the phenotype is less severe and broader, as the defect is permissive for T-lymphocyte development (Arnaiz-Villena et al., 1992; Ozgür et al., 2008; Tokgoz et al., 2013; Gokturk et al., 2014; Rowe et al., 2018; Lee et al., 2019). The age of patients ranges from early childhood to adulthood. Bacterial and viral infections, particularly of the respiratory tract are most commonly described, and atopic dermatitis is frequent. Additionally, autoimmunity is frequently encountered, particularly autoimmune thyroiditis, inflammatory bowel disease and autoimmune hemolytic anemia. Immunologically, lymphocyte numbers are generally normal, although CD3 expression is impaired. Proliferation to mitogens may be diminished. The regulatory T-lymphocyte proportion, repertoire diversity and function is also restricted in some patients, possibly accounting for the autoimmune features. Treatment with antimicrobial prophylaxis and immunosuppression has been reported—hematopoietic stem cell transplantation has been performed in a few patients.

CD4 deficiency

The CD4 molecule, a member of the immunoglobulin superfamily, is a co-receptor of the T-lymphocyte receptor and binds to distinct regions of the MHC class II molecule, defining T-helper lymphocytes. Two patients, both adults, are published to date with different homozygous mutations in *CD4*, resulting in absent or reduced protein function (Fernandes et al., 2019; Lisco et al., 2021). Both patients had severe, longstanding papillomatous warts, whilst the patient with absent CD4 protein also experienced recurrent respiratory tract infections and severe pneumonia. Immunophenotyping revealed normal CD3⁺ and CD8⁺ lymphocyte numbers but complete absence of CD4⁺ T-lymphocytes. Immunoglobulin levels were normal, although the most severely affected patient had impaired antibody responses to some vaccine antigens (Lisco et al., 2021). Interestingly, this patient had a relative expansion of CD4[−]CD8[−]TCR $\alpha\beta$ ⁺ (double negative) lymphocytes which retained phenotypic and functional characteristics of normal CD4⁺ T-lymphocytes, which included a division of naïve and memory subsets, expression of regulatory T-cell markers FOXP3 and CD25, and expression of CD40, that paralleled that of normal CD4⁺ T lymphocytes, suggesting that double negative T-lymphocytes may be able to accomplish certain specific CD4⁺ T-lymphocyte functions. Patients were treated conservatively, but in severe cases, hematopoietic stem cell transplantation would be expected to cure the disease.

CD8 α chain deficiency

The CD8 T-lymphocyte co-receptor, expressed on the cell surface as $\alpha\alpha$ chain homodimers or $\alpha\beta$ chain heterodimers, is essential for intra-thymic positive thymocyte selection, without which CD8⁺ T-lymphocytes are not released into the periphery. The expression of CD8 β on the cell surface requires expression of CD8 α ; failure to express CD8 α results in degradation of CD8 β in the

endoplasmic reticulum. Few patients with CD8 α chain deficiency are described (de la Calle-Martin et al., 2001; Mancebo et al., 2008; Dumontet et al., 2015) and younger family members sharing the same genotype and immunotype were asymptomatic. Patients present with recurrent viral and bacterial sino-pulmonary infections from early childhood, which evolve to severe bronchiectasis in later life. Immunological evaluation demonstrated normal lymphocyte numbers, with normal CD4 $^{+}$, CD19 $^{+}$ values and normal NK cells, but completely absent CD8 $^{+}$ T-lymphocytes. A high percentage of CD4-CD8-TCR $\alpha\beta^{+}$ T-lymphocytes was identified. Proliferation to mitogens was normal. Immunoglobulin levels were normal, with positive antibody responses to vaccine antigen. Optimal treatment has yet to be determined:- antibiotic prophylaxis and immunoglobulin replacement has been reported.

TCR α subunit constant chain deficiency

Most T-lymphocytes express a T-lymphocyte receptor heterodimer with extracellular and transmembrane domains consisting of α and β peptides. These associate with transmembrane and intracellular subunits of the CD3 complex. During intra-thymic development, the antigen-capture (variable) region of the T-lymphocyte receptor is constructed following random recombination of specific coding segments in the V (variable), D (diversity), and J (joining) regions of the T-lymphocyte receptor loci, which then joins with the constant subunit of the T-lymphocyte receptor α and β chains. Two patients from unrelated families are reported, who demonstrated a mutation at the base following a termination codon, initiating abnormal splicing leading to a leaky termination signal. Clinically, recurrent upper and lower sino-pulmonary tract infection led to chronic lung damage. Candidiasis, diarrhea, and growth failure were apparent. One patient experienced chronic varicella, EBV and human herpesvirus 6 infection. Hepatosplenomegaly and lymphadenopathy were present. Autoimmunity with vitiligo, alopecia and hemolytic anemia was described.

The immunotype was similar between patients. CD3 $^{+}$ T-lymphocytes expressed the $\gamma\delta$ T-lymphocyte receptor. An abnormal population of CD3 lo cells expressed the $\alpha\beta$ T-lymphocyte receptor at extremely low levels. Proliferation of lymphocytes in response to phytohemagglutinin was variably impaired. Class-switched memory B-lymphocytes were present, and immunoglobulin levels were normal (although IgE was elevated), with normal vaccine responses. Autoantibodies were also documented.

Infections responded to conventional antimicrobial treatment and did not recur upon institution of antibacterial and antifungal prophylaxis. Both patients were cured by hematopoietic stem cell transplantation (Morgan et al., 2011).

IL21 and IL21R deficiency

Interleukin 21 (IL-21) is principally produced by CD4 $^{+}$ T-lymphocytes, encompassing T follicular helper lymphocytes, as well as T_H17 T-lymphocytes. Upon ligation to the interleukin-21 receptor (IL21R), the associated constituent, the common γ chain transmit signals through the JAK-signal transducer and activator of transcription (STAT) pathways to regulate of CD4 $^{+}$ T-lymphocyte, T_H17 and Treg differentiation, CD8 $^{+}$ T-lymphocyte proliferation, B-lymphocyte cell differentiation, and NK cell cytotoxicity. IL-21 production by T follicular helper lymphocytes and increased IL-21R expression on germinal center B-lymphocyte provokes brisk B-lymphocyte proliferation, and directs immunoglobulin isotype switching and plasma cell differentiation as well as memory B-lymphocyte formation.

To date, only one consanguineous family is described with IL21 deficiency (Salzer et al., 2014). Clinically, the proband, 11 years old at the time of the report, presented with inflammatory bowel disease and failure to thrive at 2 months of age. Recurrent, severe upper and lower respiratory infections were notable through childhood and may have contributed to finger clubbing. Immunological investigations revealed raised IgE, but low IgG. T-lymphocyte numbers were normal, although there was an increase in TCR $\gamma\delta$ -bearing T-lymphocytes. B-lymphocyte numbers were low, with virtual absence of class-switched memory B-lymphocytes. A homozygous mutation in IL21 was found in a conserved residue, predicted to reduce protein stability.

Loss-of-function mutations in *IL21R* have been identified in 13 patients (Ives et al., 2013; Kotlarz et al., 2013, 2014; Erman et al., 2015; Stepensky et al., 2015; Cagdas et al., 2021). Clinical symptoms are evident in childhood, with respiratory infection and gastro-intestinal disease most common symptoms. Chronic upper and lower respiratory infection is frequently described, leading in some cases to bronchiectasis. *Pneumocystis jirovecii* infection is reported in a third of patients. Progressive cholangitis secondary to cryptosporidial infection is described in almost half of patients, leading to cirrhosis and end stage liver disease. Immunological findings are variable. T- and B-lymphocyte numbers were variably low, in the normal range or high. Class switched memory B-lymphocyte numbers were reduced and class switch induction was impaired. Immunoglobulin levels were variably low or normal, except IgM and IgE which were often raised.

Immunoglobulin replacement was offered as treatment, but the severity of the immune defect, and risk of serious lung and liver disease suggest that hematopoietic stem cell transplant should be offered early in the course of disease, particularly as mortality was seen in older patients with infection and end-organ damage.

OX40 deficiency

T-lymphocyte co-stimulatory receptor, OX40, is a member of the tumor necrosis factor superfamily and enhances T-lymphocyte receptor-induced responses. It is expressed on many activated T-lymphocytes, including CD8 $^{+}$ T-lymphocytes, and CD4 $^{+}$ T-lymphocyte subtypes:- T_H1, T_H2 and T_H17 and CD4 $^{+}$ Foxp3 $^{+}$ Tregs. Only one patient has been described to date with loss of function mutations in *OX40* (Sahin et al., 2010; Byun et al., 2013), a female from a consanguineous union who presented in

childhood with leishmaniasis, and at the age of 14 years with HHV8-associated Kaposi sarcoma. Immunological investigation demonstrated a normal number of T- and B-lymphocytes in blood. However, the naive CD4⁺ T-lymphocyte population was expanded with lower proportions of non-naive subsets, particularly for the effector memory and Treg populations. Similarly, the memory B-lymphocyte compartment was diminished. Given the high level of OX40 expressed in Kaposi sarcoma, OX40 deficiency may be selectively susceptible to this complication of HHV8 infection.

MHC class I deficiency

MHC class I molecules are transmembrane glycoprotein heterodimers constructed from α chains, the genes for which are encoded on the short arm of chromosome 6, and a β_2 microglobulin protein. MHC class I molecules present peptides derived from intracellular protein, to CD8 T-lymphocyte receptors and induce the cytotoxic T-lymphocyte response. They are important for clearing intra-cellular pathogens. Additionally, the expression of MHC I molecules on the thymic epithelial cell surface, enables positive selection of CD8⁺ T-lymphocytes during intra-thymic T-lymphocyte development. MHC I deficiency is caused by defects in the genes encoding one of the proteins essential for transporting the peptide to the endoplasmic reticulum and loading it onto the MHC I molecule, namely transporter associated with antigen processing (TAP) 1 and TAP2, and tapasin proteins. Rarely, defects in β_2 microglobulin lead to the same phenotype (Ardeniz et al., 2015; Yabe et al., 2002). Without antigen loading, the MHC I molecule is not presented at the cell surface.

Patients usually present usually during childhood with recurrent upper respiratory tract disease causing sinusitis, otitis media, nasal disease and pharyngitis. Recurrent lower respiratory tract bacterial infections cause chronic inflammatory lung disease and bronchiectasis. Sterile necrotizing granulomatous skin lesions resembling Wegeners granulomatosis are described in some patients, and may cause midface deformities. Immunological findings include diminished CD8⁺ TCR $\alpha\beta$ lymphocyte numbers. MHC I expression is severely diminished or absent. Natural killer cell numbers may be increased. Treatment is supportive with aggressive use of prophylactic antibiotics—immunoglobulin replacement may be necessary. Treatment of the granulomata can be extremely challenging and include immunosuppression with local topical steroid (Gadola et al., 2000). Hematopoietic stem cell transplant has rarely been attempted (Gao et al., 2016).

MHC class II deficiency

MHC class II molecules are transmembrane glycoprotein heterodimers constructed from α and β chains, the genes for which are on the short arm of chromosome 6. MHC class II molecules offer exogenous peptides to CD4⁺ T-lymphocyte receptors to commence the normal adaptive response. The expression of MHC II molecules on thymic epithelial cells enables positive selection of CD4⁺ T-lymphocytes during thymic development. MHC II deficiency is caused by mutations in one of four regulatory genes (*CIITA*, *REFX5*, *REFXANK*, *REFXAP*) that code for transacting regulatory factors, which are required for MHC II molecule expression on the cell surface. Mutations in any of these genes lead to a similar clinical picture.

Patients usually present at an older age than patients with classical severe combined immunodeficiency. Severe, persistent respiratory or gastrointestinal tract infections are characteristic of the disease, with infections caused by bacterial, viral, fungal or protozoal pathogens including *Pneumocystis jirovecii*. Severe sino-pulmonary infections are common. Growth failure secondary to viral-induced enteropathy is frequently encountered. Cryptosporidial liver disease is well described. Enteroviral infections are frequent and may cause meningoencephalitis. Autoimmunity, particularly autoimmune cytopenia, is a distinct feature in some patients (Ouederni et al., 2011; Al-Herz et al., 2013; Ben-Mustapha et al., 2013).

The immunophenotype includes CD4⁺ lymphocytopenia, with diminished immunoglobulin levels and impaired vaccine antibody responses. T-lymphocyte proliferative responses to phytohaemagglutinin may be normal. Most patients will not be detected by newborn screening for severe combined immunodeficiency as some TRECs are present, although occasional patients will be picked up (Marcus et al., 2018).

The only curative treatment is hematopoietic stem cell transplantation. Historically, results have been less good for this disease compared with other immunodeficiencies (Gennery et al., 2010), in part because of increased mortality from viral infection or graft versus host disease (Renella et al., 2006). Recent results are more encouraging with a variety of donor and stem cell sources (Elfeky et al., 2018; Lum et al., 2020).

ZAP-70 deficiency

The zeta-chain associated protein kinase 70 kDa (ZAP-70) is important for effective T- and B-lymphocyte receptor signaling and critical for T-lymphocyte differentiation and function (Kaur et al., 2014). Mutations in *ZAP70* cause an autosomal recessive combined immunodeficiency characterized by CD8⁺ T-lymphocytopenia. The majority of patients present in the first year of life with severe infections including *Pneumocystis jirovecii* infection, and failure to thrive (Elder et al., 1994; Turul et al., 2009). However, patients with hypomorphic mutations may present later (Picard et al., 2009), when autoimmunity may predominate (Chan et al., 2016; Sharifinejad et al., 2020). Hematological cytopenias are most common, autoimmune enteropathy and autoimmune dermatoses are described. Lymphoproliferation may be seen at an older age, and lymphoma is reported which is not invariably associated with EBV infection.

Typically, patients demonstrate normal or elevated peripheral lymphocyte numbers, associated with normal or increased CD4⁺ T-lymphocytes. Conversely, CD8⁺ T-lymphocytes are low or absent, but may increase over time suggesting development of limited thymic output, although TREC levels are very low (Roifman et al., 2010; Suresh et al., 2020). Despite normal CD4⁺ T-lymphocyte numbers, cells fail to proliferate in response to T-lymphocyte mitogen stimulation. However, by-passing stimulation of the T-lymphocyte receptor with PMA and ionomycin does induce proliferation (Elder et al., 1994). B-lymphocyte numbers are normal, although most patients are hypogammaglobulinemic.

Management of patients with ZAP-70 kinase deficiency is as for other patients with a severe combined immunodeficiency—antimicrobial prophylaxis and immunoglobulin replacement. Hematopoietic stem cell transplantation is curative (Cuvelier et al., 2016).

IKAROS deficiency

Ikaros family zinc finger 1 (*IKZF1*) encodes a transcription factor, which regulates gene transcription during hematopoietic cell development in the bone marrow, by recruiting target DNA to proteins that modify chromatin.

Heterozygous mutations in *IKZF1* have been associated with a variety of immune defects, autoimmunity and malignancy. Pancytopenia with anemia, thrombocytopenia and neutropenia portending B-lymphocytopenia and diminished NK cells is described (Goldman et al., 2012). A common variable immunodeficiency-type clinical picture with progressive B-lymphocytopenia and associated hypogammaglobulinaemia is also recognized, which is inherited in an autosomal dominant fashion with incomplete penetrance (Kuehn et al., 2016; Bogaert et al., 2018). Combined immunodeficiency with increased CD8⁺ T-lymphocyte counts but reduced regulatory T-lymphocyte numbers, a skewed T-lymphocyte receptor repertoire, with increased T-lymphocyte receptor $\alpha\beta^+$ CD4⁺ CD8⁺ double-negative T-lymphocyte counts, and impaired proliferation to mitogens are reported (Hoshino et al., 2016). Haploinsufficiency defects are associated with a common variable immunodeficiency phenotype, whereas combined immunodeficiency is associated with dominant negative mutations. Mutations leading to a dimerization defect are associated with predominantly hematological manifestations including cytopenia, but also malignancy manifesting as T-ALL and Burkitt lymphoma (Kuehn et al., 2021).

The clinical presentation is inconsistent, but severe bacterial infection, with recurrent sino-pulmonary infection described is reported, as well as infection with *Pneumocystis jirovecii*. Autoimmune hematological cytopenias, vasculitis and systemic lupus erythematosus are recognized (Kuehn et al., 2016). Treatment is directed at replacing immunoglobulin, and appropriate management of autoimmune symptoms, or of malignancy. The place of hematopoietic stem cell transplantation in selected patients is yet to be determined, although it has been successfully performed (Hoshino et al., 2016).

DOCK8 deficiency

Although previously classified as autosomal recessive Hyper IgE syndrome (Zhang et al., 2009; Engelhardt et al., 2009), patients with bi-allelic mutations in dedicator of cytokinesis 8 (*DOCK8*) are now considered to have a combined immunodeficiency, reflected in the new ISUS classification (Engelhardt et al., 2015; Aydin et al., 2015; Tangye et al., 2020). *DOCK8* is highly expressed highly in immune cells and failure of *DOCK8* function impairs T-lymphocyte proliferation, production of antiviral T_H1 cytokines, decreased production of T_H17 cytokines, and increased production of T_H2 cytokines, which is associated with allergic responses (Su et al., 2011). The immune synapse formation is impaired, which disrupts antiviral NK cell cytotoxicity.

Patients can present from infancy with severe bacterial, viral and fungal infections. Typical clinical features include eczema, recurrent sinopulmonary infections, recurrent or severe viral skin infections (particularly Herpes simplex, severe molluscum contagiosum and severe human papilloma virus infections), and malignancy (Aydin et al., 2015) often leading over time to end organ damage. Bronchiectasis may develop from recurrent pneumonias. Severe food allergies are common in patients with *DOCK8* deficiency and maybe associated with anaphylaxis. Common bacterial pathogens include *Staphylococcus aureus* and *Streptococcus pneumoniae*. *Pneumocystis jirovecii* can cause interstitial pneumonitis. Mucocutaneous candidiasis is frequently reported. Vasculitis is well described, including cerebral vasculitis. Malignancies are common, and include lymphoma, associated with chronic EBV infection, and squamous cell carcinoma associated with chronic HPV infection. Severe eczema is one of the most common complications. Asthma is also common.

Immunological features include a highly elevated IgE and eosinophilia. IgG and IgA levels can be normal or high, IgM levels are often progressively reduced. Vaccine antibody responses may be subnormal and isohemagglutinins diminished or absent. T-lymphocyte subsets are diminished, and B-lymphocyte counts reduced with low or absent class switched memory B-lymphocytes. NK cell counts can be reduced (Engelhardt et al., 2015; Aydin et al., 2015). Some patients with *DOCK8* deficiency may be detected at birth by newborn screening for severe combined immunodeficiency, due to low or absent TRECs (Dasouki et al., 2011).

Aggressive treatment of infection is key, and antimicrobial prophylaxis is required. Immunoglobulin replacement is recommended. However, even with these conservative measures, the long term prognosis is poor with survival less than 40% by 30 years of age, and event-free survival (life-threatening infection, central nervous system involvement, malignancy or death) only 4% by 30 years of age (Aydin et al., 2015). Hematopoietic stem cell transplantation is therefore considered the treatment of choice for these patients, with 84% survival in a large multi-center cohort (Aydin et al., 2019). Although most manifestations respond well to transplantation, resolution of food allergy is variable (Happel et al., 2016; Aydin et al., 2019).

DOCK2 deficiency

Like DOCK8, Dedicator of cytokinesis 2 (DOCK2) is primarily expressed in hematopoietic cells and has an important role in the reorganization of the actin cytoskeleton. Few patients have been described to date, with loss of function mutations in *DOCK2*. The predominant clinical phenotype appears to be combined immunodeficiency with viral susceptibility, particularly to varicella, and mycobacterial infection. One kindred presented with 'leaky' SCID phenotype, and a further patient had a raised IgM. The immunophenotype shows T-lymphocytopenia and impaired in vitro T-lymphocyte activation in response to phytohemagglutinin. Naïve T-lymphocytes were reduced, with diminished TREC numbers on dried blood spots taken at birth. Immunoglobulins are generally normal, with impaired vaccine responses. Hematopoietic stem cell transplantation appears to be curative (Dobbs et al., 2015; Alizadeh et al., 2018; Moens et al., 2019).

Polymerase (DNA-Directed), DELTA 1, catalytic subunit (POLD1) and DELTA 2, regulatory subunit (POLD2) deficiency

DNA polymerase delta (POLD) is indispensable for leading and lagging DNA strand synthesis, and in mammals is a heterotetramer composed of four subunits: POLD1 is a catalytic subunit with polymerase and exonuclease functions and is critical in several synthetic and DNA repair processes. POLD2, with POLD3 and POLD4 regulate the activity of the complex by stabilizing the structure, establishing protein-protein interactions, and regulating the cell cycle. Heterozygous mutations in the POLD1 exonuclease domain are reported in patients with inherited colorectal cancers. A heterozygous deletion in the catalytic domain, that disrupts DNA polymerase activity but preserves exonuclease activity, is described in patients with a developmental disorder of mandibular hypoplasia, sensorineural hearing loss, progeria-like features, and lipodystrophy with insulin resistance. More recently, patients with a combined immunodeficiency have been described, who have T-lymphocytopenia with a CD8 oligoclonal repertoire restriction. The defect appears to confer impaired T-lymphocyte development and survival, consistent with the role that POLD plays in DNA repair. One patient with a combined immunodeficiency phenotype has been described with mutations in POLD2. The optimum treatment pathway for these patients has yet to be determined (Conde et al., 2019; Cui et al., 2020; Nichols-Vinueza et al., 2021).

RHOH deficiency

The ras homolog family member H is an essential negative regulator of hematopoietic cell growth and survival. To date, only two adult patients have been described with bi-allelic loss-of-function mutations in *RHOH*. The defining clinical phenotype was characterized by severe and persistent Epidermodysplasia verruciformis from early childhood—one patient experienced less severe molluscum (Crequer et al., 2012a). Burkitt lymphoma developed in one patient. The immunological phenotype demonstrated normal T-lymphocyte counts with slightly reduced CD4⁺ T-lymphocytes and high CD8⁺ T-lymphocytes. Recent thymic emigrants were severely diminished. There was restricted TCR usage with clonal expansion of certain Vβ families. Lymphocyte proliferation was impaired after stimulation through the T-lymphocyte receptor. Immunoglobulin levels and vaccine antibody responses were normal. Treatment for these patients was symptomatic—however, the T-lymphocytopenia was corrected in mice by hematopoietic stem cell transplantation, suggesting that this treatment modality may have utility in human patients.

Serine-threonine protein kinase 4 deficiency (Mammalian sterile 20-like protein deficiency)

The serine/threonine kinase 4 gene (*STK4*) encodes Mammalian sterile 20-like protein (MST1), which has a central role in regulating lymphocyte homing, cell survival and proliferation. Bi-allelic loss-of-function mutations have been described in a few individuals (Nehme et al., 2012; Abdollahpour et al., 2012; Crequer et al., 2012b; Dang et al., 2016; Sherkat et al., 2017; Schipp et al., 2018; Moran et al., 2019; Al-Saud et al., 2019b; Ashrafi et al., 2020; Radwan et al., 2020; Jørgensen et al., 2021). Clinical features are varied, but severe lower respiratory infection with bacterial infection is common. Skin manifestations are frequent including extensive molluscum contagiosum, eczema, recurrent skin abscesses, and significant human papillomavirus infection. In some patients, mucocutaneous candida infection was a feature. Autoimmune cytopaenias have been documented in a few patients. Lymphoma, commonly but not invariably associated with EBV, has been described in a number of individuals.

A variable but consistent lymphocytopenia is observed, and in some patients, CD4⁺ lymphocytopenia was remarkable. Low numbers of naïve T-lymphocytes are present. B-lymphocyte numbers are generally normal, and immunoglobulin levels were normal or high. Autoantibodies were present in some patients. Intermittent neutropenia has been a significant feature in several patients.

Treatment with antimicrobial prophylaxis and immunoglobulin replacement was effective for some patients, but given the severity of the combined immunodeficiency, hematopoietic stem cell transplantation seems a reasonable approach and has been successful for a few patients.

LCK deficiency

The lymphocyte-specific LCK protein, which is encoded by *LCK*, is a protein-tyrosine kinase of the SRC oncogene family. It is important for transduction through the T-lymphocyte receptor. The p56(LCK) protein is plasma membrane-bound and cooperates

with intracellular domains of CD4⁺ and CD8⁺ co-receptors. There are only a few reports of mutations in *LCK* in patients. A young female who had homozygous mutations in *LCK* is reported. From infancy, she had failure to thrive secondary to chronic diarrhea. She presented with recurrent respiratory tract infections, and experienced pneumonia complicated by a pneumatocele. In early childhood, she had multiple nodular skin lesions diagnosed as neutrophilic panniculitis with interphalangeal joint inflammation accompanied by daily fevers (Hauck et al., 2012). Immunologically, there was a profound CD4⁺ T-lymphocytopenia with a diminished proportion of TCRαβ⁺ T-lymphocytes and increased TCRγδ⁺ T-lymphocytes. B-lymphocyte and NK cell counts were normal or slightly low. A further patient with a common variable immunodeficiency phenotype is reported with CD4⁺ T-lymphocytopenia and an aberrantly spliced *LCK* transcript lacking exon 7 of *LCK* (Sawabe et al., 2001). The same defect was found in an infant with severe combined immunodeficiency, who presented with oral candidiasis and rotavirus-associated diarrhea and poor weight gain (Goldman et al., 1998). *Enterobacter cloacae* was isolated from the blood, and cytomegalovirus from the urine and intestinal biopsies. Hematopoietic stem cell transplantation was successful in this patient, but although the first patient underwent hematopoietic stem cell transplantation, she succumbed to complications (Bader-Meunier et al., 2018).

Interleukin-2- inducible T-lymphocyte kinase deficiency

Interleukin-2-inducible T-lymphocyte kinase (ITK), encoded by *ITK*, is involved in T-lymphocyte receptor activation, signaling and proliferation. Upon T-lymphocyte receptor activation, ITK moves to the cell membrane, activates PLCγ1, causing intracellular calcium release and activation of nuclear factor κB (NF-κB), mTOR, and MAPK/ERK intracellular pathways.

Patients with mutations in *ITK* characteristically present with EBV-associated lymphoproliferation and are highly susceptible to developing EBV-related lymphoma—nine of sixteen (56%) in a review of ITK-deficient patients developed lymphoma (Fig. 4), (Ghosh et al., 2018). Other features included EBV-driven hemophagocytic lymphohistiocytosis, and CMV or varicella infection. Epidermodysplasia Verruciformis has also been described (Youssefian et al., 2019). Autoimmune features were documented in three patients, and autoimmune lymphoproliferative syndrome is described (Wallace et al., 2021). Pulmonary interstitial nodules have been described in many patients (Huck et al., 2009; Stepensky et al., 2011; Linka et al., 2012; Mansouri et al., 2012; Ghosh et al., 2014; Serwas et al., 2014; Alme et al., 2015; Bienemann et al., 2015; Cipe et al., 2015; Cagdas et al., 2017). CD4⁺ T-lymphocytopenia is present in most patients, although CD3⁺ and CD8⁺ lymphocyte values were normal. Natural Killer T-cells, when measured, were reduced. Progressive hypogammaglobulinemia was documented in some patients. Hematopoietic stem cell transplantation seems curative, and should be offered to these patients once malignancy has been controlled—pre-emptive transplant is likely to prevent malignancy (Ghosh et al., 2018).

CARD11/BCL10/MALT1 (CBM) complex deficiencies

NF-κB is a critical component of lymphocyte activation, survival, proliferation and inflammatory cytokine production. Upstream physiological regulation of NF-κB activation is co-ordinated by a protein complex composed from caspase activation and recruitment domain 11 (CARD11), B-cell CLL/lymphoma 10 (BCL10) and mucosa associated lymphoid tissue lymphoma translocation protein 1 (MALT1), the CBM complex. Loss-of-function and gain-of-function mutations in the *CARD11*, *BCL10*

Fig. 4 Chest radiograph of a 4 year old child with ITK deficiency demonstrating extensive bilateral pulmonary nodules of variable sizes. Biopsy of the nodules demonstrated an EBV-driven lymphoproliferative disorder. Courtesy of the Bubble Foundation, UK.

and *MALT1* genes encoding these protein components are reported in a few patients (Snow et al., 2012; Greil et al., 2013; Jabara et al., 2013; Stepensky et al., 2013; McKinnon et al., 2014; Torres et al., 2014; Turvey et al., 2014; Pérez de Diego et al., 2015; Frizinsky et al., 2019; Van Den Rym et al., 2020).

Autoimmune features are prominent in these diseases, particularly severe inflammatory bowel disease and enteropathy in *MALT1* and *BCL10* deficiency, but severe eczematous dermatitis is also reported (Wiegmann et al., 2020). Periodontal disease including aphthous ulcers, cheilitis, and gingivitis is described. Infection is also a prominent feature—particularly sino-pulmonary infections due to bacterial, viral and fungal pathogens—infection with *Pneumocystis jirovecii* is reported in patients with *CARD11* mutations. Atopy is described in a few patients (Fig. 5).

The immunotype shows wide variation. The lymphocyte numbers are generally normal, although B-lymphocytopenia has been described in a patient with *MALT1* deficiency. Regulatory T-lymphocytes and T_H17 lymphocytes are generally reduced in *CARD11*-deficient patients, but normal in *MALT1*-deficient patients. The patients with *BCL10* deficiency showed a profound hypogammaglobulinemia, and progressive hypogammaglobulinaemia is found in *CARD11*-deficiency, with absent antibody responses to vaccine antigens. In *MALT1*-deficient patients, immunoglobulin levels are normal, and antibody response to vaccine antigen is variable. In *CARD11* dominant negative mutations, B-lymphocytosis is reported with diminished class switch memory B-lymphocytes (Dadi et al., 2018; Desjardins et al., 2018).

Optimum treatment is yet to be determined—antimicrobial prophylaxis and immunoglobulin replacement may be of some value, but there are a few reports of successful hematopoietic stem cell transplantation for patients with *CARD11* or *MALT1* defects (Punwani et al., 2015; Rozmus et al., 2016; Charbit-Henrion et al., 2017).

IKBKB deficiency

Activation of cells of the immune system requires complex signaling to tightly regulate transcription of genes required for activation, proliferation, differentiation, survival and signaling. The key regulators are the nuclear NF- κ B transcription factors, the canonical pathway for which operates through signaling via immune receptors, including T- and B-lymphocyte receptors, tumor necrosis factor α (TNF- α) and interleukin-1 β receptors and toll-like receptors. In the non-activated state, NF- κ B molecules are maintained in latent form in the cytoplasm by molecules of the I κ B family. Upon signaling, the complex comprising IKK1, IKK2, and NEMO (which are encoded by *IKBKA*, *IKBKB*, and *IKBKG*, respectively), phosphorylates I κ B α , enabling it to undergo partial degradation in the proteasome, leading to liberation of the NF- κ B molecules RelA, c-Rel, and p50 which translocate to the nucleus as transcription factors. Several individuals have been described with bi-allelic loss of function mutations in *IKBKB* (Pannicke et al., 2013; Nielsen et al., 2014; Burns et al., 2014; Cuvelier et al., 2019; Alsum et al., 2020; Qin et al., 2021). Clinical features include delayed separation of the umbilical cord stump, as well as recurrent infections with a range of bacterial, viral and fungal micro-organisms. Many patients had localized or disseminated infection with BCG, or other atypical mycobacteria. In a few patients, the presence of conical teeth was noted. The immunotype demonstrates normal T- and B-lymphocyte numbers, with naïve cells present, normal T-lymphocyte receptor repertoire and proliferations. Class switched memory B-lymphocytes were low in some patients. IgM was variably low, normal or high—other immunoglobulin isotypes were low. Hematopoietic stem cell transplantation has been curative, and death in early childhood seems common without curative treatment.

Four patients from two families have been described with heterozygous gain of function mutations in *IKBKB* (Cardinez et al., 2018). Recurrent sinopulmonary infection was reported in all patients, with one developing bronchiectasis. Subcutaneous abscesses and mucocutaneous candidiasis were also reported. Ectodermal dysplasia was reported in one. The immunological findings included variable lymphopenia, but absent class switched memory B-lymphocytes and variable hypogammaglobulinemia. Treatment was symptomatic.

RelA deficiency

RelA mediates activation of NF- κ B through the canonical pathway, and is activated through stimulation of various cell membrane receptors including tumor necrosis factor receptor, IL-1 receptor, Toll-like receptors, and the T- and B-lymphocyte receptor. To date, five patients from two families have been described with heterozygous loss of functions in *RELA* causing haploinsufficiency. In the first family, four individuals had mucocutaneous ulceration, and two had bowel disease (Badran et al., 2017). In the second, the clinical features were of autoimmune lymphoproliferative syndrome, with tri-lineage cytopenias, and episodes of aseptic meningitis (Comrie et al., 2018). The immunotype described from two patients was limited but largely unremarkable, although the patient with autoimmune lymphoproliferative syndrome had increased activated CD4⁺ T-lymphocytes and decreased naïve T-lymphocytes.

c-Rel deficiency

c-Rel is a member of the NF- κ B family of transcription factors and, with RelA, mediates activation through the canonical pathway and binds to gene promoters encoding for cytokines including IL-2, IFN γ , IL-12, IL-21, and IL-23. One patient is described to date with a homozygous loss of function mutation in *REL*. Clinically, the patient presented in early childhood, with chronic infectious diarrhea associated with multiple pathogens, including *Salmonella enterica*, cytomegalovirus, and *Cryptosporidium* leading to sclerosing cholangitis. *Mycobacterium tuberculosis* osteomyelitis subsequently developed, despite prior vaccination with BCG. Immunologically, there were increased numbers of CD4⁺ and CD8⁺ T-lymphocytes and decreased memory T-lymphocytes and

Fig. 5 (A) NF- κ B canonical signaling pathway, demonstrating the role of CARD11, MALT1, BCL10, IKK2, c-Rel and RelA. (B) NF- κ B non-canonical signaling pathway, demonstrating the role of NIK and RelB.

associated reduced mitogen-induced T-lymphocyte proliferation. There was also B lymphocytopenia, hypogammaglobulinemia and non-protective antibody titers to the tetanus and diphtheria vaccines. Treatment was with intravenous immunoglobulin replacement and prophylactic antibiotics and the patient was evaluated for hematopoietic stem cell transplantation (Beaussant-Cohen et al., 2019).

NIK deficiency

NF- κ B inducing kinase (NIK), encoded by mitogen-activated protein kinase 14 (*MAP3K14*), is integral to the non-canonical NF- κ B signaling pathway to assimilate signals from tumor necrosis factor alpha receptor family members. A number of signaling molecules activate this pathway, including receptor activator of NF- κ B ligand (RANKL), B-cell activating factor (*BAFF*), CD40L, TNF-like weak inducer of apoptosis (TWEAK) and lymphotoxin beta (LT β). Binding of the ligand to the appropriate receptor enables phosphorylation of I κ B kinase- α (IKK α) and leads to activation of downstream signaling proteins and formation of heterodimeric RelB-p52 complexes, which enter the nucleus to activate target genes. This pathway is important for activation of dendritic cells, for B-lymphocyte maturation and lymphoid organogenesis. Only seven patients have been described to date with three homozygous loss of function mutations in *MAP3K14* (Willmann et al., 2014; Schlechter et al., 2017; Ben Farhat et al., 2019). All presented in childhood with symptoms of combined immunodeficiency, including recurrent respiratory infections leading to bronchiectasis, gastrointestinal infections, and in one case, post-vaccination disseminated BCG infection. Lymphoid tissue is scarce or absent. The characteristic immunophenotype is hypogammaglobulinaemia. T-lymphocyte numbers are reported as variably low, normal or high, although class switched memory B-lymphocytes are low. Two patients received hematopoietic stem cell transplantation—in one full immune reconstitution was documented (Ben Farhat et al., 2019).

RelB deficiency

NF- κ B activation through the non-canonical pathway is mediated by RelB, which is downstream of NIK, and is activated by the same molecules, namely RANKL, *BAFF*, CD40L, TWEAK and LT β , although simultaneous activation of the canonical pathway is observed. Three patients from an extended family of Irish descent have been described to date with homozygous stop-gain mutations in *RELB* (Merico et al., 2015). All presented in early infancy with recurrent sinopulmonary infections, including multiple episodes of lobar pneumonia—other features included ecthyma gangrenosum in one patient and arthritis in one patient. The immunotype demonstrates expanded circulating T-lymphocytes, but diminished naïve T-lymphocytes, determined by TREC quantification. Thymic biopsy from one patient showed a hypoplasia and dysplasia with disorganized cortico-medullary architecture and absent Hassall's corpuscles. T-lymphocyte proliferations to mitogens were diminished. Although all patients had increased B-lymphocyte numbers and cells responded to the T-lymphocyte independent mitogen, *Staphylococcus aureus* Cowan, which implies that there was no fundamental block in B-lymphocyte proliferation, immunoglobulin levels were variable, T-lymphocyte dependent antibody responses to vaccine antigens were low to absent, and activated and class switched memory B-lymphocyte numbers were diminished (Sharfe et al., 2015). B-lymphocytes appeared to exhibit maturational arrest, and had reduced BAFF receptor expression. Two patients underwent hematopoietic stem cell transplantation—both immune reconstituted although thymic output remained low, and one developed a recrudescence of arthritis 18 months after transplant (Ovadia et al., 2017).

Moesin deficiency

Moesin is one of three members of the ezrin-radixin-moesin (ERM) protein family, with ezrin and radixin, that connect cortical actin filament C-terminal domains to the cell plasma membrane. Moesin is expressed strongly in the hematopoietic system where it maintains cell rigidity, predominately in circulating lymphocytes. Chemotaxis and T-lymphocyte receptor and B-lymphocyte receptor signaling stimulate prompt ERM protein dephosphorylation enabling relaxation of the cytoskeleton and cell polarization. Moesin is important for the immunologic synapse formation by microclustering of the antigen receptor. Nine male patients have been described with heterozygous loss of function mutations in *MSN* on the X chromosome. Clinically, patients present in childhood, with recurrent bacterial and viral infections, particularly recurrent respiratory infections, and severe *Varicella* and *Molluscum contagiosum* infection. Autoimmune manifestations included cytopenias, alopecia and thrombotic thrombocytopenic purpura (Lagresle-Peyrou et al., 2017; Bradshaw et al., 2018). The immunotypes demonstrated pan-lymphocytopenia with reduced naïve T-lymphocytes, detectable on newborn bloodspot screening (Delmonte et al., 2017). There was pan-hypogammaglobulinemia with diminished or absent antibody responses to vaccine antigens. Patients received immunoglobulin replacement, and one successfully underwent hematopoietic stem cell transplantation. At the time of report, all patients were alive aged 4–69 years.

TFRC deficiency

The cell surface receptor, transferrin receptor 1, is required for receptor-mediated endocytosis of iron, which is critical for lymphocyte development and proliferation. Bi-allelic loss of function mutations in *TFRC* have been described in 23 individuals from the Middle East (Jabara et al., 2016; Aljohani et al., 2020; Whangbo et al., 2021). Characteristic clinical features from infancy and early childhood included recurrent respiratory infection, gastrointestinal infection with failure to thrive, and less commonly sepsis and viral meningitis, autoimmunity and hemophagocytic lymphohistiocytosis in one patient. There was a significant family history of childhood death. T-lymphocytes were of normal number, as were naïve T-lymphocytes, but B-lymphocytes were low with diminished or absent class switched memory B-lymphocytes. There was pan-hypogammaglobulinemia. Additionally, intermittent thrombocytopenia and neutropenia was noted, and mild anemia. Dysmyelopoiesis was described in a few patients. Thirteen patients underwent successful and curative hematopoietic stem cell transplantation.

FCHO1 deficiency

The internalization of molecules and proteins across cellular membranes is dependent on clathrin-mediated endocytosis. The *F-BAR domain only protein 1* (FCHO1) is key in the early events of clathrin-mediated endocytosis formation. Fifteen patients are described with bi-allelic loss of function mutations in *FCHO1* (Calzoni et al., 2019; Lyszkiewicz et al., 2020). Clinical presentation was characterized by severe bacterial, viral or fungal infections, Respiratory infection was predominant. Four patients developed B-cell lymphoma. Immunological investigation revealed CD4⁺ and CD8⁺ T-lymphocytopenia. B-lymphocyte numbers were variably low to normal, but patients had hypogammaglobulinemia. Hematopoietic stem cell transplantation is curative.

Conclusion

The exploration of immune function networks from the discovery of previously undescribed disease-causing gene mutations helps predict other uncharacterized diseases and broaden our understanding of the immune connectome. Of diseases above that have been identified and described for the longest periods of time, and for which there are large patient cohorts, the functional defect, natural history and current optimal treatment pathways are well established. For the more newly described diseases, much more information is required before we can confidently recommend the best investigative and treatment approach—for many of the diseases above, only a few patients are described, it is not apparent if these represent the dominant clinical and immunological phenotype, or rather are extremely severe examples of a more common disease manifestation. Furthermore, we should be aware of the impact of the internal and external environment on disease manifestation. For the newly described diseases, patients may come from specific ethnic and geographical backgrounds, and often from single kindred's, and so the disease manifestation may not represent that of patients with the same disease in other parts of the world.

The advent of next-generation sequencing has transformed our ability to interrogate emerging phenotypes, coupled with our realization that the manifestations of immunodeficiencies are much broader than simply infection susceptibility, and include predisposition to some lymphomas, as well as autoimmunity. Despite the growing list of new combined immunodeficiencies, there are many more molecules involved in lymphocyte development, differentiation and activation, and it is certain that the current list will continue to grow.

Wiskott-Aldrich syndrome and other congenital Thrombocytopenias	470
DNA repair defects	470
Ataxia-telangiectasia	470
Nijmegen breakage syndrome	471
Bloom syndrome	471
Immunodeficiency, centromeric instability, facial anomalies (ICF) syndrome	471
Other CID syndromes with DNA repair defects	471
CID associated with thymic defects	472
DiGeorge syndrome (22q11.2 del; TBX1 deficiency)	472
CHARGE syndrome, a multiorgan disorder with AD inheritance	472
Winged helix nude FOXP1 deficiency	472
CID associated with immuno-osseous dysplasia	473
Cartilage-hair hypoplasia	473
Schimke immuno-osseous dysplasia	473
Other immuno-osseous dysplasia syndromes that have in common short stature, skeletal anomalies and recurrent infections	473
Hyper IgE syndromes	473
STAT3 LOF mutations with dominant negative effect, also known as Job syndrome	473
DOCK8 deficiency	474
Phosphoglucomutase 3 (PGM3) deficiency	474
CARD11 deficiency	474
Disrupted STAT3 transcription by biallelic mutations in the <i>ZNF341</i> gene	474
Defects in IL-6 signaling mimicking AD-HIES	475
HIES imitators	475
Defects of vitamin B12 and folate metabolism	475
Transcobalamin 2 deficiency	476
Biallelic mutations in SLC46A1	476
Methylene-tetrahydrofolate dehydrogenase 1 (MTHFD1) deficiency	476
Anhidrotic ectodermal dysplasia	476
Mutations in the <i>IKBKG</i> gene	476
Heterozygous gain of function (GOF) mutations in NFKBIA	476
Heterozygous GOF mutation in the IKBKB gene	476
Calcium channel defects	477
Purine nucleoside phosphorylase (PNP) deficiency	477
Hepatic veno-occlusive disease with immunodeficiency (VODI)	477
Other CID disorders with syndromic features	477
Immunodeficiency with multiple intestinal atresia due to biallelic mutations in the <i>TTC7A</i> gene	477
Tricho-Hepato-Enteric syndrome (THES) caused by biallelic mutations in <i>TTC37</i> or <i>SKIVL2</i>	477
Neurologic deficiencies associated with CID	477
HOIL1 and HOIP deficiency	478
STAT5B deficiency	478
Kabuki syndrome	478
References	478

Combined immune deficiencies (CID) with syndromic features are a subgroup of primary immune deficiency (PID) disorders, also known as inborn errors of immunity (IEI), caused by single gene defects. Affected patients have in common an increased susceptibility to bacterial, viral and opportunistic infections, and, in addition, may suffer from growth retardation, connective tissue pathology, ectodermal dysplasia, cardiac malformation, intestinal atresia, autoimmunity, radiosensitivity, chromosomal instability or an increased incidence of malignancies (Tangye et al., 2020). Of note, the symptoms suggesting immune deficiency may have delayed onset and develop gradually over time. To address the extent of the immune defect, a basic assessment of the patient's adaptive and innate immune systems is important for implementing proper preventive therapy. A detailed patient and family history may reveal signs and symptoms of possible immunodeficiency and syndromic features suggesting a genetic origin with autosomal recessive (AR) or autosomal dominant (AD) inheritance (Table 1). A carefully executed examination to detect syndromic features in a patient with a history of chronic infections is the preferred approach to recognize and eventually molecularly

Table 1 Syndromic features, genetic and immunologic defects

Disease and combined immunodeficiencies with syndromic features	Genetic defect	OMIM	Inheritance	Immunologic defects		
				T	B	Immunoglobulins specific antibodies
1. Congenital thrombocytopenia						
(a) Wiskott-Aldrich Syndrome Bloody diarrhea, eczema, bacterial, viral infections, autoimmunity, malignancies, small platelets	WAS	300392	XL	Lymphopenia, decreased proliferation to anti-CD3	Normal numbers	IgA and IgE elevated, depressed antibody responses to some antigens
(b) X-linked thrombocytopenia Milder form of WAS	WAS	313900	XL	Decreased proliferation to anti-CD3	Normal	IgA, IgE elevated
(c) WIP deficiency WAS phenotype, WAS protein is absent, but mRNA is present	WIPF1	602357	AR	Lymphopenia Poor response to anti-CD3	Normal	IgA, IgE elevated
(d) ARP2/3 deficiency WAS phenotype, vasculitis, SCID-like	ARPC1B	604223	AR	Normal numbers	Normal numbers	IgA, IgE elevated
2. DNA repair defects						
(a) Ataxia Telangiectasia (A-T) Sino-pulmonary infections. Progressive cerebellar ataxia, ocular and skin telangiectasia; chromosomal instability, radiosensitivity, malignancies; increased alpha fetoprotein	ATM	607585	AR	Lymphopenia, may have low TRECS at NBS, low mitogen responses	Variably reduced	Low except for normal or elevated IgM, abnormal antibody responses by some patients
(b) Nijmegen breakage syndrome (NBS) respiratory infections. Microcephaly, dysmorphic features; chromosomal instability, radiosensitivity, malignancies, normal alpha fetoprotein	NBS1	602667	AR	Progressive lymphopenia, low TRECs at NBS	Variably reduced	Low, except for normal or elevated IgM, antibody responses may be decreased
(c) Bloom syndrome (BS) Mild bacterial infections; short stature, dysmorphic facies, sun sensitive erythema; chromosomal instability, lymphoma/leukemia; normal alpha fetoprotein	BLM	604610	AR	Normal	Normal	Hypogammaglobulinemia (in some)
(d) Immunodeficiency, centromeric instability, facial anomalies (ICF syndrome) Recurrent bacterial, viral, opportunistic infections; formation of multi-radial chromosomal figures; malignancies; hypomethylation			AR	Normal, or low numbers and function	Normal or decreased	Hypogammaglobulinemia, variable antibody deficiency
• Type 1	DNMT3B	602900				
• Type 2	ZBTB24	614064				
• Type 3	CDCA7	609937				
• Type 4	HELLS	603946				
(e) PMS2 deficiency Recurrent infections; increased risk for malignancies	PMS2	600259	AR	Normal	Decreased	Hypogammaglobulinemia, elevated IgM
(f) Radiation sensitivity, immunodeficiency, dysmorphic features, learning difficulties (RIDDLE Syndrome) Short stature, microcephaly; occasionally ataxia telangiectasia and increased alpha fetoprotein	RNF168	612688	AR	Normal	Normal	Hypogammaglobulinemia
(g) DNA ligase 1 deficiency Growth retardation; sun and radiation sensitivity	LIG1	126391	AR	Decreased, mitogen responses low	Normal	Hypogammaglobulinemia, Abnormal antibody responses

3. CID associated with thymic defects							
(a) DiGeorge syndrome (22q11.2 deletion syndrome) Abnormal facies; hypoparathyroidism; cardiac malformation	<i>Large deletion 22q11.2</i>	188400	AD	Normal or decreased, low TRECs at NBS	Normal	May have abnormal antibody responses	
(b) TBX1 deficiency DiGeorge phenotype	<i>TBX1</i>	602054	AD	Normal or decreased, low TRECs at NBS	Normal	May have abnormal antibody responses	
(c) CHARGE syndrome Coloboma, heart defect, choanal atresia, growth retardation, genital and ear abnormalities,	<i>CHD7</i>	608892	AD	Decreased, low TRECs, ±SCID-like	Normal	May have hypogammaglobulinemia	
(d) Winged helix nude FOXN1 deficiency Bacterial and viral infections; congenital alopecia, nail dystrophy; abnormal thymic epithelium	<i>SEMA3E</i>	608166	AD				
(e) FOXN1 haploinsufficiency Mild viral infections; often nail dystrophy; symptoms improve with age	<i>FOXN1</i>	601705	AR	Decreased, low TRECs at NBS; no CD45RA	Normal	Hypogammaglobulinemia, Abnormal antibody responses	
4. CID associated with immuno-osseous dysplasia							
(a) Cartilage hair hypoplasia (CHH) Bacterial, viral fungal infections; growth failure, hair hypoplasia; neuronal dysplasia (colon), bone marrow failure; autoimmunity; malignancies	<i>FOXN1</i>	618806	AD	Low at birth, low TRECs at NBS	Normal	Normal	
(b) Schimke immuno-osseous dysplasia Bacterial, viral, fungal infections; short stature, spondyloepiphyseal dysplasia; nephropathy;	<i>RMRP</i>	157660	AR	Decreased or normal; decreased TRECs at NBS	Normal	Immunoglobulin levels normal or reduced, specific antibodies may be normal or decreased	
(c) Other osseous dysplasia syndromes	<i>SMARCAL1</i>	606622	AR	Low CD45RA, low mitogen responses	Normal	Reduced antibody responses	
• MYSM1 deficiency	<i>MYSM1</i>	612176	AR	Decreased, low CD45RA	Block in early B cell development	Hypogammaglobulinemia, reduced antibody response	
• MOPD1 deficiency	<i>RNU4ATAC</i>	601428	AR	decreased NK cell function	Low memory B cells	Hypogammaglobulinemia, reduced antibody response	
• EXTL3 deficiency	<i>EXTL3</i>	617425	AR	decreased	Normal	Low or normal Ig's	
5. Hyper IgE syndromes (HIES)							
(a) STAT3 (LOF) deficiency (Job syndrome) bacterial, fungal infections, mucocutaneous candidiasis, boils; pulmonary abscesses, pneumatoceles; neonatal onset eczema, coarse facial features, hyperextensible joints, scoliosis, pathologic fractures, retained primary teeth;	<i>STAT3</i>	147060	AD Dom. Neg.	Th17 lymphopenia	Reduced memory and switched B Cells	High IgE, reduced antibody responses	
(b) DOCK8 deficiency Bacterial respiratory infections, cutaneous viral infections; squamous cell carcinoma; eczema, allergies (food), asthma; CNS manifestations (aneurisms, vasculitis)	<i>DOCK8</i>	243700	AR	T lymphopenia Low (±) TRECs at NBS, low responses to mitogens	Reduced numbers of memory B cells	High IgE, reduced antibody responses	
(c) ZNF341 deficiency Clinical phenotype of AD STAT3 deficiency due to disrupted STAT3 transcription	<i>ZNF341</i>	618282	AR	Th17 lymphocytes Decreased	Reduced memory and switched B cells	High IgE, decreased antibody responses	
(d) IL-6 signaling defects Clinical phenotype of AD STAT3 deficiency		147880					
• IL-6 receptor deficiency	<i>IL6R</i>	618523	AR	normal	Low switched B	High IgE, low antibody	
• IL-6 signal transducer (GP130) deficiency	<i>IL6ST</i>	617638	AR	Th17 cells low	Low switched memory B cells	High IgE, decreased antibody responses	

(Continued)

Table 1 (Continued)

Disease and combined immunodeficiencies with syndromic features	Genetic defect	OMIM	Inheritance	Immunologic defects		
				T	B	Immunoglobulins specific antibodies
(e) PGM3 deficiency Bacterial, viral, fungal infections; allergies; fascial dysmorphism, skeletal abnormalities; neurologic manifestations	PGM3	172100	AR	Decreased (±)	Decreased total and memory B cells	IgE often elevated
(f) CARD11 deficiency Bacterial, viral infections of skin; early onset asthma, food allergies, eczema; some with autoimmunity and cytopenia; variable penetrance	CARD11	617638	AD (LOF)	Low mitogen and anti-CD3 responses,	Normal	High IgE, reduced antibody responses
(g) Comel-Netherton syndrome Bacterial infections; congenital ichthyosis, bamboo hair; atopic diathesis	SPINK5	605010	AR	Normal	Low switched memory B cells	High IgE, decreased antibody responses
6. Defects of vitamin B12 and folate metabolism						
(a) Transcobalamin 2 deficiency Bacterial, viral infections, PJP; megaloblastic anemia; pancytopenia, hyper segmented neutrophils	TCN2	613441	AR	Decreased	Decreased	Hypogammaglobulinemia, reduced antibody response
(b) PCFT deficiency causing folate malabsorption Bacterial, viral infections, PJP; megaloblastic anemia	SLC46A1	229050	AR	Decreased	Decreased	Hypogammaglobulinemia
(c) MTHFD1 (a folate-dehydrogenase) deficiency Bacterial, viral infections, PJP; megaloblastic anemia, neutropenia	MTHFD1	172460	AR	Decreased	Decreased	Decreased antibody responses
7. Anhidrotic Ectodermal Dysplasia with Immunodeficiency (EDA-ID)						
(a) IKBKG (NEMO) deficiency Variable phenotype, including bacterial, atypical mycobacterial, viral, fungal infections; colitis; variable defects of skin, hair, teeth (conical)	IKBKG	300248	XL	Normal or decreased, impaired function	Reduced memory and switched B cells	Often decreased, some with elevated IgM, abnormal antibody responses
(b) EDA-ID due to heterozygous GOF mutation in IKBA Bacterial, viral, fungal infections; colitis; variable defects of skin, hair, teeth (conical)	NFKBIA	164008	AD GOF	Normal, impaired function	Reduced memory and switched B cells	Decreased with elevated IgM, abnormal antibody responses
(c) EDA-ID due to GOF mutation in IKBKB Bacterial, viral, fungal infections; variable ectodermal defects; can be SCID-like	IKBKB	618204	AD GOF	Decreased number and function	Normal numbers Reduced function	Hypogammaglobulinemia
8. Calcium channel (CRAC) defects						
(a) ORAI1 deficiency Bacterial, viral, fungal infections; EDA; autoimmunity; congenital myopathy	ORAI1	160277	AR	Impaired T cell activation, NK function reduced	Normal	Abnormal antibody responses
(b) STIM1 deficiency Phenotype similar as ORAI1 deficiency	STIM1	605921	AR	Impaired T/NK cell function	Normal	Abnormal antibody responses
9. Purine nucleoside phosphorylase (PNP) deficiency Bacterial, opportunistic infections; autoimmunity; neurologic defects	PNP	164050	AR	Decreased, reduced function	Normal or low	Hypogammaglobulinemia
10. Hepatic veno-occlusive disease with immunodeficiency (VODI) Opportunistic infections; thrombocytopenia; hepatosplenomegaly	SP110	604457	AR	Normal, decreased memory T cells	Decreased memory B cells	Hypogammaglobulinemia
11. Other CID disorders with syndromic features						
(a) Immunodeficiency with multiple intestinal atresia, Bacterial, fungal, viral infections; intrauterine polyhydramnios; may be SCID-like	TTC7A	609332	AR	Low or absent, low TRECs at NBS	Normal or low	Hypogammaglobulinemia

(b) Tricho-Hepato-Enteric Syndrome (THES) Respiratory infections; facial dysmorphism, growth retardation; wooly hair; diarrhea; liver disease	<i>TTC37</i>	222470	AR	Impaired IFN γ production	Decreased switched memory B cells	Hypogammaglobulinemia abnormal antibody responses
	<i>SCIV2L</i>	614602	AR			
(c) Neurologic deficiencies associated with CID Recurrent infections; developmental delay, absent corpus callosum; cutaneous manifestations				low TRECs at NBS, low CD4 SCID-like	Normal Abnormal function	Normal Hypogammaglobulinemia
• BCL11B deficiency	<i>BCL11B</i>	617237	AD			
• EPG5 deficiency (Vici syndrome)	<i>EPG5</i>	615068	AR			
(d) Defects of the Linear Ubiquitination chain Assembly Complex (LUBAC) Bacterial infections; autoinflammation; amylopectinosis						
• HOIL1 deficiency	<i>RBCK1</i>	610924	AR	Normal	low memory B	Hypogammaglobulinemia
• HOIP deficiency	<i>RNF31</i>	612487	AR	Normal	cells	abnormal antibody responses
(e) STAT5B deficiency Bacterial, viral infections, interstitial pneumonitis; short stature due to growth hormone insensitivity; dysmorphic features	<i>STAT5B</i>	245590	AR	Decreased, reduced Treg function	normal	Hypogammaglobulinemia elevated IgE
(f) Kabuki Syndrome Respiratory infections, typical facial features (long palpebral fissures); skeletal abnormalities, high arched palate, short stature; congenital heart defects,	<i>STAT5B</i>	604260	AD Dom. Neg.	Normal	normal	Elevated IgE
• Type 1	<i>KMT2D</i>	602113	AD	Normal	Normal	Low IgA and occasionally low IgG
• Type 2	<i>KDM6A</i>	300128	XL	Normal	Normal	

define these unique syndromes. To address the extent of the adaptive immune deficiency, the number and function of B and T cells have to be evaluated including quantitation of serum immunoglobulins (IgG, IgA, IgM, IgE), lymphocyte subset analysis, and assessment of in vitro lymphocyte proliferation to mitogens, anti-CD3 and specific antigens such as candida and tetanus toxoid (Table 1). Dependent on the extent of the immune deficiency, appropriate therapies can be initiated, including prophylactic antibiotics or antivirals, IgG replacement, biologics, hematopoietic stem cell transplantation (HSCT) or gene therapy (GT).

Wiskott-Aldrich syndrome and other congenital Thrombocytopenias

As originally described by Wiskott (Wiskott, 1937), classic Wiskott-Aldrich Syndrome (WAS) is characterized by the triad of recurrent bacterial and viral infections, eczema and hemorrhagic diathesis secondary to congenital micro-thrombocytopenia. The syndrome was subsequently expanded to include increased risk for autoimmunity and hematologic malignancies (Albert et al., 2011). The discovery of the WAS gene (Derry et al., 1994) allowed the identification of variable clinical phenotypes in addition to “classic” WAS, namely X-linked thrombocytopenia (XLT), a mild form of WAS with close to normal life expectancy but dismal event-free survival (Albert et al., 2010a), and X-linked-neutropenia (XLN) due to mutation in the Cdc42 binding domain of the WAS gene (Beel et al., 2009). WAS, XLT and XLN are X-linked disorders caused by mutations in the WAS gene that encodes the WAS-protein (WASP) which is expressed only in hematopoietic stem cell derived lineages.

WASP is stabilized by WASP-interacting protein (WIP). Mutations in the *WIPF1* gene result in unstable (absent) WASP and a clinical phenocopy of classic WAS while the sequence of the WAS gene and mRNA expression are normal (Lanzi et al., 2012; Schwinger et al., 2018). Activated cytoplasmic WASP links signaling pathways to actin cytoskeleton reorganization by inducing actin polymerization. This process is mediated by actin-related protein (ARP) 2/3, coded for by *ARPC1B*. Biallelic mutations in the *ARPC1B* gene result in a WAS-like clinical phenotype characterized by congenital micro-thrombocytopenia, eczema, vasculitis, inflammatory bowel disease (IBD) and recurrent infections. Most patients with *ARPC1B* deficiency develop eosinophilia, elevated serum IgA and IgE and autoantibodies similar to WAS patients. (Kahr et al., 2017). Other single gene defects characterized by actinopathy and congenital thrombocytopenia include AR mutations in the *WDR1* (Pfajfer et al., 2018) and *RASGRP1* genes (Salzer et al., 2016), and several other genes recently reviewed (Etzioni and Ochs, 2020). Each of these actinopathy/thrombocytopenia entities has to be molecularly confirmed by sequencing the causative genes.

Treatments for patients with CID associated with thrombocytopenia and actinopathy include conventional measures such as prophylactic antibiotics and antiviral agents, IgG replacement for patients with demonstrated antibody deficiency, and trauma prevention measures. Platelet transfusions are reserved for major bleeding episodes (acute CNS hemorrhage, gastrointestinal bleeding or during major surgery). Thrombopoietin receptor agonists have been used with some success in WAS/XLT patients while waiting for HSCT (Khoreva et al., 2021; Gerrits et al., 2015). Elective splenectomy for WAS/XLT patient will result in increased platelet number, but is not recommended because of an increased risk to develop septicemia (Lum et al., 1980). HSCT is a readily available curative treatment for WAS/XLT patients with excellent overall survival (Burroughs et al., 2020). Gene therapy is an alternative, potentially curative, therapy under investigation (Ferrua et al., 2019).

DNA repair defects

Ataxia-telangiectasia

Ataxia-telangiectasia (A-T) is an autosomal recessive multisystem disorder characterized by progressive neurological impairment, oculocutaneous telangiectasia, variable CID resulting in recurrent sinopulmonary infections, cancer susceptibility and sensitivity to ionizing irradiation, making A-T a prominent example of DNA repair defects (Rothblum-Oviatt et al., 2016). The worldwide incidence of A-T is estimated to be 1:40,000 to 100,000 live births, more frequent in countries with founder effect mutations, such as Poland and Costa Rica. A-T is caused by biallelic mutations in the *ATM* gene which encodes a protein (ATM) that is involved in the cellular responses to DNA double strand breaks (DSB), genomic stability, checkpoint control and cell cycle regulation. Cerebellar ataxia is generally the presenting symptom and becomes apparent at age 1–2 years when an affected child begins to walk and the gait remains ataxic with truncal movements. The ataxia is progressive affecting the extremities, speech, swallowing, and eventually requiring the use of a wheelchair. Telangiectasias develop typically during childhood between 3 and 6 years of age. Predisposition to sinopulmonary infections occurs in up to 80% of A-T patients. Recurrent episodes of pneumonia may progress to bronchiectasis, pulmonary fibrosis, eventually leading to cor pulmonale and premature death. The recurrent infections are the result of combined immunodeficiency which is characterized by hypogammaglobulinemia, except for elevated IgM levels due to defective class switch recombination (CSR). In vitro lymphocyte proliferation to mitogens and antigens is generally impaired. The characteristic chromosomal instability and frequent translocations involving chromosomes 12 and 14 have been associated with the high incidence of leukemia and lymphoma (Hecht et al., 1973).

The diagnosis of A-T is based on the characteristic clinical presentation and laboratory findings that include elevated serum α -fetoprotein levels beyond early infancy, decreased IgA, IgG and often elevated IgM, abnormal antibody production, lymphopenia, radiosensitivity, chromosomal instability and chromosomal translocation. Lymphopenia may be present at birth, resulting in low T cell receptor excision circles (TREC) at newborn screening (NBS). The diagnosis is confirmed by mutation analysis of the *ATM* gene, which allows the differentiations of A-T from the A-T like disorder (ATLD) caused by mutations in the *MRE11* gene, which encodes a

double-stranded repair nuclease, and from other DNA repair defects (none of which has elevated α -fetoprotein) (Yel et al., 2014). Therapy is symptomatic including antibiotic prophylaxis and IgG replacement. Irradiation, either naturally or by diagnostic X-ray, should be avoided.

Nijmegen breakage syndrome

The clinical hallmarks of Nijmegen Breakage Syndrome (NBS) patients are severe microcephalic growth retardation, typical facial appearance, CID, radiosensitivity and increased risk for malignancies. NBS is an AR multisystem disorder with similarities to A-T (Chrzanowska et al., 2012). The microcephaly, due to the stunted growth of the brain, is present in most cases at birth. Lack of sexual maturation is a frequently seen consequence, especially in girls. Susceptibility to infections varies greatly but respiratory infections are reported by most patients and may result in bronchiectasis or chronic lung disease (Wegner et al., 2014). The immune deficiency, if present, affects both humoral and cellular immunity. Some NBS patients have normal serum immunoglobulin levels, others may present with hypogammaglobulinemia, elevated IgM due to defective CSR, and decreased antibody production. In vitro responses of lymphocytes to mitogens and/or specific antigens are variably defective. In contrast to A-T, α -fetoprotein is normal in NBS patients. Most but not all NBS patients have features of chromosomal instability, such as chromosomal rearrangements involving chromosomes 7 and 14, possibly linked to the predisposition to malignancies, which are mostly of lymphoid origin (B and T cell lymphoma). NBS is caused by biallelic mutations in the *NBS1* gene, making a molecular diagnosis possible. The gene product, nibrin, forms the complex MRE11-RAD50-Nibrin which detects DSB of DNA and activates ATM. Treatment is symptomatic and includes IgG replacement if antibody deficiency is present. HSCT has been successfully performed in selected cases (Albert et al., 2010b).

Bloom syndrome

The most consistent physical features of Bloom Syndrome is the small but well-proportioned stature, dysmorphic facial features, a sun-sensitive erythematous “butterfly” rash, infertility, susceptibility to bacterial infections and early development of lymphoid malignancies and cancer (colon, skin, breast) (Cunniff et al., 2017). The immunodeficiency in Bloom Syndrome patients is mild, consisting of hypogammaglobulinemia, but generally normal antibody responses to immunizations and normal lymphocyte proliferation to mitogens and specific antigens. The chromosomes of phytohemagglutinin (PHA) stimulated lymphocytes of Bloom Syndrome patients develop large numbers of characteristic and diagnostic sister chromatid exchanges (SCE). Bloom Syndrome is caused by biallelic mutations in the *BLM* gene which encodes BLM, a DNA helicase involved in DNA replication and repair. Mutations in the *BLM* gene are rare, except in the Ashkenazi Jewish populations where as many as 1:110 individuals is a carrier. Treatment is symptomatic, antibiotics for acute infections, IgG replacement if antibody deficient, and sun protection. Avoiding irradiation, and close observation for malignancies is recommended (Wegner et al., 2014).

Immunodeficiency, centromeric instability, facial anomalies (ICF) syndrome

This rare AR syndrome is often associated with consanguinity, and characterized by mild facial anomalies that include hypertelorism, epicanthic folds, broad flat nasal bridge, low set ears, macroglossia, immunodeficiency and chromosomal instability (Hagleitner et al., 2008). Infections are more frequent and severe than in other DNA repair defects. Recurrent episodes of pneumonia are frequently caused by gram positive and gram negative bacteria, but may include opportunistic infections such as *Pneumocystis jirovecii* (PJ), CMV, JC virus and candida. Hypogammaglobulinemia, abnormal antibody responses and T cell function have been reported. Centromeric instability involving chromosomes 1, 9 and 16 are characteristic findings in cultured lymphocytes and include gaps, breaks, deletions and multiradial figures. The common pathogenic mechanism of ICF appears to be hypomethylation caused by defective DNA methyl transferase activity. To date, 4 genes causing ICF have been identified, *DNMT3B* (ICF1 present in 60% of ICF patients), *ZBTB24* (ICF2, 25%), *CDCA7* (ICF3, 5%) and *HELLS* (ICF4, 5%) (Thompson et al., 2018; Unoki et al., 2019).

Other CID syndromes with DNA repair defects

Genetic disorders included in this group of rare syndromes characterized by genomic instability have in common defects in the DNA repair machinery that utilizes cell cycle checkpoints to stop cell cycle progression in the presence of DNA damage. Since DNA repair mechanisms are also responsible for DNA rearrangements required for the generation of highly diverse T and B cell antigen receptors, defects in this process result in abnormal adaptive immunity associated with characteristic syndromic features. Increased radiosensitivity and susceptibility to cancer, recurrent bacterial and viral infections, facial dysmorphism and short stature are common features (van Gent et al., 2001).

Disorders assigned to this category have AR inheritance and include:

- PMS2 is involved in the mismatch repair machinery and plays a role in CSR-induced DSB generation. As a result of biallelic mutations in the *PMS2* gene, affected patients present with hypogammaglobulinemia except for elevated IgM, and are at high risk for malignancies (Peron et al., 2008).

- Biallelic mutations in the *RNF168* gene causes a syndrome characterized by Radiosensitivity, Immunodeficiency, Dysmorphic features, Learning Difficulties (RIDDLE). *RNF168* participates in the repair mechanism of DNA DSB (Stewart et al., 2009). Affected patients present with short stature, mild ataxia, and occasionally develop microcephaly, telangiectasia and increased serum levels of α -fetoprotein. The immune deficiency is mild and limited to hypogammaglobulinemia, rarely resulting in chronic lung disease. A-T has to be considered in the differential diagnosis (Devgan et al., 2011).
- MCM4 deficiency is associated with short stature, adrenal insufficiency, recurrent infections including viral infections (EBV, herpes simplex and varicella—zoster virus), and an increased incidence of B cell lymphoma. MCM4 functions as a DNA helicase that is required for DNA replication and cell proliferation. The prominent immune defect involves NK cells that are low in number and function (Hughes et al., 2012).
- POLE1 and POLE2 deficiencies, caused by biallelic mutations in polymerase ϵ subunit 1 and 2, are characterized by facial dysmorphism, short stature due to intra-uterine growth retardation, telangiectasia, recurrent bacterial and viral infections, hypogammaglobulinemia, lymphopenia, low B cell numbers, and decreased in vitro lymphocyte proliferation (Logan et al., 2018). Mutations in POLE1 cause FILS syndrome (Fascial dysmorphism, Immunodeficiency, Livedo, Short stature) often presenting at birth with discolored skin of cheeks and upper and lower extremities known as livedo (Pachlopnik Schmid et al., 2012). POLE2 deficiency causes more extensive T cell defects that may result in absent TRECs at NBS, disseminated BCG, and autoimmune diseases (type 1 diabetes and hypothyroidism).
- DNA Ligase 1 deficiency, caused by biallelic mutations within *LIG1*, presents with growth retardation/short stature and sun sensitivity. This rare syndrome is the consequence of defective repair of DNA DSB via homologous recombination, resulting in lymphopenia, decreased T cell proliferation, hypogammaglobulinemia and macrocytic red blood cells. The severity of the symptoms can vary considerably. Patients with severe T cell deficiency may require HSCT (Maffucci et al., 2018).
- ERCC6L2 (Hebo) deficiency is associated with facial dysmorphism, microcephaly and may progress to bone marrow failure. Lymphopenia affecting both B and T cells is a common finding. ERCC6L2 is a helicase involved in chromatin unwinding, transcription regulation and DNA recombination, translocation and repair (Zhang et al., 2016).
- Patients with GINS1 deficiency present with intrauterine growth retardation, mild facial dysmorphism, recurrent bacterial and viral infections, lymphopenia (affecting both T and B cells), low NK cell number and neutropenia that responds to G-CSF treatment. Hypogammaglobulinemia except for normal or elevated IgA is a common feature (Cottineau et al., 2017).

CID associated with thymic defects

DiGeorge syndrome (22q11.2 del; *TBX1* deficiency)

The thymus and parathyroid glands originate from the 3rd and 4th pharyngeal arches which interact with the cardiac neural crest during the 4th week of embryonic development. Disruption of this process results in CID associated with AD thymic defects known as DiGeorge/velocardiofacial syndrome (chromosome 22q11.2 deletion syndrome, or heterozygous *TBX1* deficiency), characterized by thymic aplasia, hypoparathyroidism, conotruncal cardiac malformation and mild to moderate immunodeficiency, defined as predominant T cell defect with secondary abnormalities in B cell function (Sullivan, 2019). The spectrum of CID is broad, ranging from near normal T cell numbers and function to a partial DiGeorge anomaly with susceptibility to bacterial and viral infections to complete DiGeorge syndrome with SCID/Omenn like features requiring a thymic transplant (Deshpande et al., 2021). The *TBX1* gene, located within the 22q11.2 deletion, encodes a transcription factor, that, if mutated on a single allele, is responsible for a syndrome with many features of DiGeorge anomaly. If associated with severe lymphopenia, the DiGeorge syndrome may present with low numbers of TRECs at NBS. The decreased serum concentration of Ca^{++} and phosphorus may cause tetany. If severely lymphopenic and if T cell function is absent, life vaccines are contraindicated.

CHARGE syndrome, a multiorgan disorder with AD inheritance

CHARGE syndrome is caused by heterozygous mutations in the *CHD7* or *SEMA3E* genes, presenting with growth retardation, coloboma, heart defects, atresia of the choanae, genital hypoplasia and CNS malformation (van Ravenswaaij-Arts et al., 1993). Treatment is symptomatic; experimental thymic transplants have shown promising results (Legendre et al., 2017).

Winged helix nude *FOXP1* deficiency

Biallelic mutations in the transcription factor *FOXP1* result in severe respiratory viral and bacterial infections, congenital alopecia, nail dystrophy and erythroderma. *FOXP1* acts as master regulator of thymic epithelial development and its absence is responsible for athymia and CD4 lymphopenia, absence of CD45RA lymphocytes and low TRECs at NBS, resulting in combined immune deficiency. In addition, *FOXP1* plays a crucial role in the differentiation of keratinocytes and hair follicles. HSCT and thymic transplantation have resulted in immune reconstitutions in a subset of patients (Gallo et al., 2017). Heterozygous pathogenic mutations were found in a cohort of infants with very low TRECs at NBS associated with severe T cell lymphopenia which persisted through infancy. Nail dystrophy and mild viral infection were noted in half of these infants. With age, the lymphopenia and symptoms resolve, except for nail dystrophy that persists in some adults with *FOXP1* haploinsufficiency (Bosticardo et al., 2019; Auricchio et al., 2005).

CID associated with immuno-osseous dysplasia

This group of syndromic CID patients presents with spondyloepiphyseal dysplasia associated with intra/extrauterine growth retardation, dysmorphic facial features and variable immune defects resulting in recurrent bacterial and viral infections.

Cartilage-hair hypoplasia

Cartilage-hair hypoplasia due to biallelic mutations in the *RMRP* gene is characterized by short-limbed growth failure due to metaphyseal dysplasia, hair hypoplasia (thin and sparse hair growth), neuronal dysplasia of the colon resembling Hirschsprung anomaly, impaired spermatogenesis and increased risk of malignancies. The *RMRP* gene encodes the untranslated RNA component of the mitochondrial RNA-processing endoribonuclease which contributes to cell cycle regulation and telomere maintenance. The extend of immune deficiency varies and may present as congenital lymphopenia (low TRECs at NBS) and impaired lymphocyte proliferation to mitogens, hypogammaglobulinemia and antibody deficiency. Approximately half of reported cases present with increased susceptibility to bacterial infections, such as URI, pneumonia, sepsis, and meningitis, but may also suffer from viral (CMV, EBV, parvovirus, varicella-zoster virus, HSV) and fungal (aspergillus) infections. Chronic lung disease, including bronchiectasis, fibrosis, emphysema and asthma are common complications (Vakkilainen et al., 2020). Treatment depends on the extend of immune deficiency and frequency of infections. Anti-microbial therapy, IgG replacement, attention to early onset GI—disease and observation for malignancies are part of symptomatic treatment. HSCT has been reported to successfully cure the immune defect but with only 62% long term survival (Bordon et al., 2010).

Schimke immuno-osseous dysplasia

Schimke immuno-osseous dysplasia, due to biallelic mutations in *SMARCA1*, is a rare multisystem disorder characterized by growth retardation, spondyloepiphyseal dysplasia, nephropathy often progressing to renal failure, and frequent bacterial, viral and fungal infections (Bertulli et al., 2020). *SMARCA1* encodes a chromatin remodeling helicase that is considered a genome maintenance protein. Most patients have low numbers of recent thymic emigrants, decreased number and function of T cells, absence of IL-7 R α expression and reduced humoral immune responses. Treatment is symptomatic. Renal transplantation has been successfully performed but the outcome of HSCT has been dismal (Baradaran-Heravi et al., 2013).

Other immuno-osseous dysplasia syndromes that have in common short stature, skeletal anomalies and recurrent infections

- MYSM1 deficiency is a rare syndrome, observed in consanguineous Middle East families, presenting with progressive bone marrow failure, myelodysplasia, gingival hyperplasia, cataracts, and developmental aberrations. Recurrent respiratory tract infections, associated with lymphopenia, reduced number of naive T cells and hypogammaglobulinemia, require antibiotic prophylaxis unless curative HSCT can be performed. MYSM1 is a transcriptional regulator mediating histone deubiquitination (Bahrami et al., 2017).
- Roifman syndrome, also known as MOPD1 deficiency, is caused by biallelic mutations in the *RNU4ATAC* gene, and is characterized by extreme intra-uterine growth retardation, retinal dystrophy, facial dysmorphism and microcephaly. Decreased NK cell function, low memory B cell numbers, hypogammaglobulinemia and antibody deficiency are responsible for the frequent bacterial infections that are typical for this syndrome (Merico et al., 2015).
- Immuno-skeletal dysplasia with neurodevelopmental abnormalities is caused by biallelic mutations in the *EXTL3* gene and typically presents with hypogammaglobulinemia, recurrent bacterial infections, lymphadenopathy, retinal dystrophy and intrauterine growth retardation (Volpi et al., 2017).

Hyper IgE syndromes

Hyper IgE syndromes (HIES) are a group of single gene defects characterized by eczema, recurrent infections, combined immuno-deficiency and elevated serum IgE (Al-Shaikhly and Ochs, 2019).

STAT3 LOF mutations with dominant negative effect, also known as Job syndrome

Neonatal onset eczema is present in 57% of affected patients and recurrent cutaneous staphylococcal infections in the form of “cold” abscess formation develop in 74%. Recurrent episodes of pneumonia caused predominately by staph aureus (72%) and *Aspergillus fumigatus* (27%) often result in pneumatoceles. Deep organ abscesses and mucocutaneous candidiasis are the direct result of defective innate and adaptive immunity. Non-immunologic manifestations include characteristic facial features, retained primary teeth (41%), hyper-extensible joints (8.5%), scoliosis (34%), recurrent pathological fractures (39%) and vascular anomalies (aneurisms) (Gernez et al., 2018). Based on these clinical findings, combined with elevated IgE and eosinophilia, the NIH-HIES scoring system was designed to accurately diagnose the syndrome (Grimbacher et al., 1999). In most cases, the IgE

levels start to rise shortly after birth, reaching 2000–100,000 IU/mL, often decreasing, or even normalizing during adulthood. IgE concentration does not correlate with disease severity. IgG, A, M are normal, but antibody responses are defective and B cell maturation is impaired as exemplified by decreased CD27⁺ switched memory B cells (Meyer-Bahlburg et al., 2012). Heterozygous loss of function (LOF) mutations in the DNA binding domain, SH2 domain and transactivation domain, resulting in a non-functional STAT3 protein that is no longer capable of forming dimers or penetrating the nuclear membrane and act as a transcription factor, thus generating a dominant negative effect with only 25% of normal STAT3 function (Renner et al., 2008). Treatments include prophylactic anti-staphylococcal and anti-fungal agents, meticulous skin care and IgG replacement if antibody deficiency is present. The aim is to prevent pneumatocele formation and the permanent loss of lung function. HSCT, performed on an experimental basis, has given conflicting results (Goussetis et al., 2010).

DOCK8 deficiency

DOCK8 Deficiency typically results in atopic diathesis. Affected patients present with eczema, allergies (85% have food allergies) and often suffer from asthma. Due to pronounced combined immune deficiency, DOCK8 deficient patients develop recurrent bacterial and fungal sinopulmonary infections, and are highly susceptible to cutaneous viral infections, most frequently herpes simplex virus (HSV), human papilloma virus (HPV) and molluscum contagiosum. Persistent HPV infection may be responsible for the high prevalence of vulvar and head/neck squamous cell carcinoma. Neurologic manifestations include CNS-infections, vasculitis, aneurysms, and brain infarcts. (Aydin et al., 2015). Besides elevated IgE and eosinophilia, the finding of T cell lymphopenia, reduced naïve CD8⁺ and increased exhausted CD8⁺ T cells, low numbers of NK and regulatory T (Treg) cells with decreased function, depressed mitogen responses, reduced memory B cells and decreased antibody responses indicates a SCID phenotype. DOCK8 deficiency is caused by biallelic deletions spanning multiple exons of the *DOCK8* gene or less frequently by point mutations, leading to premature stop codons and resulting in lack of protein expression, allowing rapid diagnosis by flow analysis. DOCK8 acts upstream of WASP and regulates cytoskeletal rearrangement required for cell-migration and synapse formation (Randall et al., 2009). Since DOCK8 is expressed uniquely in hematopoietic stem cell derived cellular elements, early HSCT is highly successful and curative (Aydin et al., 2015).

Phosphoglucomutase 3 (PGM3) deficiency

PGM3-deficient patients share characteristic features of STAT3 and DOCK8 deficiency including facial dysmorphism and skeletal abnormalities, allergies, and recurrent bacterial, viral, and fungal cutaneous infections. As has been observed in other glycosylation disorders, neurologic manifestations (developmental delay, ataxia) distinguish PGM3-deficient patients from other HIES (Zhang et al., 2014). Lymphopenia affecting both T and B cells (but with normal or elevated immunoglobulin levels), reduced mitogen responses and neutropenia are responsible for recurrent infections. Since PGM3 is involved in protein glycosylation, loss of function mutations causes a broad spectrum of clinical manifestations. Treatment is symptomatic. Oral *N*-acetyl glucosamine supplementation has been implemented in a few cases, with some positive results. HSCT was performed successfully in two patients (Stray-Pedersen et al., 2014).

CARD11 deficiency

Genetic evaluation of a group of patients with severe atopy (early onset asthma, eczema, food allergies) and recurrent bacterial and viral infections revealed heterozygous missense mutations with dominant negative effect in caspase recruitment domain family member (CARD)11, a scaffold protein that plays a critical role in T and B cell signaling via NF- κ B and mTor activation. Affected patients have normal immunoglobulin levels, except for elevated IgE. In vitro lymphocyte proliferation to mitogens and anti-CD3 is decreased and antibody responses are depressed, indicating combined immune deficiency (Dadi et al., 2018). A recent analysis of 48 patients from 27 unrelated families expanded the clinical phenotype to include IPEX-like symptoms of autoimmunity and cytopenias, and immunologic defects resembling those seen in STAT3 loss of function, DOCK8 deficiency and CVID (Dorjbal et al., 2019).

Disrupted STAT3 transcription by biallelic mutations in the *ZNF341* gene

ZNF341 is a transcription factor that binds to a specific DNA motif within the STAT3 promotor, controlling transcription, translation, and production of the STAT3 protein. As a result of ZNF341 deficiency, only a small amount of STAT3 is generated in response to STAT3-activating cytokines, resulting in a clinical phenocopy resembling AD-HIES. All affected patients reported to-date have been the offspring of consanguineous marriages and presented with recurrent infections, reduced memory B cells, decreased antibody production, high serum IgE and IgG levels, and decreased numbers of Th17 cells (Frey-Jakobs et al., 2018; Beziat et al., 2018). Treatment is symptomatic and includes antimicrobial compounds, as recommended for AD-HIES patients.

Defects in IL-6 signaling mimicking AD-HIES

IL-6, a proinflammatory cytokine, interacts with a multi-subunit receptor complex by directly binding to its receptor (IL-6R) resulting in the ligation of the signal-transducer subunit (IL6ST) also known as glycoprotein 130 (GP130) transducer chain, leading to JAK and STAT-phosphorylation, the dimerization of pSTAT3 and its nuclear import resulting in transcription of genes involved in cell growth and differentiation.

Loss of the IL-6R due to homozygous mutations was reported in two unrelated patients, presenting with atopic dermatitis, skin abscesses (described as lacking the formation of erythema), bacterial infections, hypogammaglobulinemia, very high IgE levels, eosinophilia and markedly elevated serum IL-6 (Spencer et al., 2019).

Loss of function mutations in the *IL6ST* gene, encoding GP 130, result in a clinical phenotype resembling AD STAT 3 deficiency. Two unrelated patients were identified to have homozygous missense mutations each involving a different codon (Shahin et al., 2019); both were offspring of consanguineous marriages. A cohort of 12 patients from 8 unrelated kindreds had an AD-HIES phenotype due to seven different truncating heterozygous *IL6ST* mutations with dominant negative effect (Beziat et al., 2020). STAT3 phosphorylation in response to stimulation with GP130-dependent cytokines was impaired in patient lymphocytes and monocytes.

HIES imitators

In addition to the “classic” HIES with a characteristic clinical phenotype and interconnected molecular mechanisms, there is a group of patients with distinct clinical symptoms and laboratory findings that resemble in part the classic HIES phenotype (Al-Shaikhly and Ochs, 2019).

- Patients with atypical complete DiGeorge syndrome due to 22q11.2 deletion may develop an Omenn-like phenotype with recurrent respiratory infections, erythematous rash, elevated IgE and eosinophilia, restricted T cell repertoire and lymphadenopathy, in addition to hypocalcemia and congenital heart disease (Vu et al., 2013).
- Omenn syndrome is a distinct autoinflammatory disorder associated with genetically diverse leaky SCID-causing gene mutations. Affected infants develop viral and fungal infections, chronic diarrhea, severe erythroderma, enlarged lymphoid organs, increased IgE levels and eosinophilia. The process is triggered by oligoclonal T cells with autoreactive activity. Treatment is symptomatic, HSCT is curative (Villa et al., 2008).
- WAS is an X-linked disorder with variable clinical phenotypes that correlate with type and location of mutations in the *WAS* gene (Ochs and Thrasher, 2006) (see Section “Wiskott-Aldrich syndrome and other congenital Thrombocytopenias” of this review). Patients with “classic WAS” present with recurrent bacterial, viral, and fungal infections, microthrombocytopenia and bleeding tendency, eczema, autoimmune symptoms, and increased risk of malignancies. The CID of WAS is characterized by abnormal function of B, T, NK and T regs cells; serum IgA and IgE and the number of eosinophils are elevated.
- Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX), is a rare PID caused by hemizygous mutations in the *FOXP3* gene which encodes the transcription factor FOXP3 responsible for the generation of regulatory T (Treg) cells. IPEX is a member of the increasing family of Primary Immune Regulatory Disorders (PIRD), but, unlike most HIES, susceptibility to infection is not a prominent complication. Affected males present early in life with autoimmune endocrinopathies (type 1 diabetes, hypothyroidism) and cytopenias, enteropathy and eczema. Eosinophilia and elevated IgA and IgE are common findings. Most IPEX patients have reduced or lack completely CD4+CD25+FOXP3+Treg cells (Torgerson and Ochs, 2007). While Rapamycin and other immunosuppressive agents effectively turn down the overactive immune system, the only curative treatment is HSCT (Barzaghi et al., 2018).
- Comel-Netherton syndrome, an AR disorder caused by mutations in *SPINK5* encoding LEKTI, is characterized by increased bacterial infections, congenital ichthyosis, bamboo hair, atopic diathesis, elevated IgE and eosinophilia. Based on the finding of reduced switched memory B cells and abnormal antibody responses, IVIG therapy has been initiated in a cohort of Comel-Netherton patients with marked improvement of symptoms (Renner et al., 2009).
- Heterozygous loss of function mutations with dominant negative effect in *CARD14* were associated with severe atopic dermatitis, skin infections, asthma, and food allergies in four members of three non-related families, resulting in decreased NFκB signaling. IgE levels were persistently very high (Peled et al., 2019).
- Severe atopic dermatitis is the most common cause of elevated IgE and needs to be differentiated from HIES caused by single gene defects. The immune system is generally intact in non-specific atopic disease and the bacterial and viral infections are the consequence of a defective skin barrier and rarely result in deep abscesses, organ infections or immune dysregulation (Wollenberg et al., 2003).

Defects of vitamin B12 and folate metabolism

Vitamin B12 and folate (vitamin B9) play critical roles in cellular metabolism. Deficiencies of these vitamins affect rapidly proliferating cell populations such as hematopoietic stem cell derived lineages that provide adaptive immunity and generate

phagocytes. Three single gene defects affecting cobalamin or folate uptake and transport into cells have been identified in patients with clinical symptoms of immune deficiency. (Watkins and Rosenblatt, 2020).

Transcobalamin 2 deficiency

Transcobalamin 2 deficiency, caused by biallelic mutations in *TCN2*, interrupts the delivery of B12 to bone marrow cells, causing megaloblastic anemia, pancytopenia including low numbers/decreased function of T and B cells, and neutropenia with hyper-segmented granulocytes. Recurrent infections, such as candidiasis and Pneumocystis Jirovecii Pneumonia (PJP), improve when affected patients are treated parenterally with high dose Vitamin B12 (Unal et al., 2019).

Biallelic mutations in SLC46A1

Biallelic mutations in *SLC46A1* encoding the proton-coupled folate transporter (PCFT) result in hereditary folate malabsorption. In addition to megaloblastic anemia, patients develop variable B and T cell deficiencies and recurrent infections including oral candidiasis, PJP, hypogammaglobulinemia (Borzutzky et al., 2009).

Methylene-tetrahydrofolate dehydrogenase 1 (MTHFD1) deficiency

Methylene-tetrahydrofolate dehydrogenase 1 (MTHFD1) deficiency is associated with low thymic output, decreased B cell numbers and abnormal antibody responses, neutropenia, megaloblastic anemia and PJP. Treatment with oral folic acid corrects the hematologic and immunologic abnormalities (Ramakrishnan et al., 2016).

Anhidrotic ectodermal dysplasia

Anhidrotic ectodermal dysplasia with immunodeficiency (EDA-ID) is caused by molecular defects in the NF-KB pathway. Typical findings are sparse hair, conical teeth and absent sweat glands associated with various degrees of combined immunodeficiency. In unstimulated normal cells the NF-KB complex is sequestered in the cytoplasm by the inhibitory protein, IKBA (I κ B α) which is encoded by *NFKBIA*. Activation of the upstream I κ B kinase (the complex IKK α /IKK β /IKK γ) induces the proteolytic degradation of IKBA and enables the NF-KB complex (p50, p65/c-Rel) to translocate into the nucleus where it activates the transcription of cytokine associated genes (Heller et al., 2020).

Mutations in the *IKBKG* gene

Mutations in the *IKBKG* gene also known as NF κ B essential modulator (NEMO) lead to the X-linked form of EDA-ID. The clinical phenotype and extend of the immune deficiency vary substantially and depend on the severity of the NEMO mutation (Heller et al., 2020). Most patients with NEMO mutations suffer from bacterial infections, and some, in addition, from infections with atypical mycobacteria, viruses, and parasites. T and NK cell function can be normal or depressed, T cell activation is often impaired, and the number of memory and isotype switched B cells may be decreased. Hypogammaglobulinemia and decreased antibody responses are observed in half the NEMO deficient patients. Carrier females with non-functional heterozygous mutations may develop incontinentia pigmenti.

Heterozygous gain of function (GOF) mutations in NFKBIA

Heterozygous gain of function (GOF) mutations in *NFKBIA* impairs the degradation of its product, IKBA and results in AD EDA-ID. Most patients have a severe clinical phenotype and guarded prognosis. (Schimke et al., 2013).

Heterozygous GOF mutation in the *IKBKB* gene

Heterozygous GOF mutation in the *IKBKB* gene that encodes IKK β was found in two unrelated families with ectodermal dysplasia, decreased T cell number and function, impaired T cell receptor (TCR) activation, hypogammaglobulinemia and recurrent bacterial and candida infections (Cardinez et al., 2018). A different clinical phenotype, resembling SCID, was observed in members of four families of Northern Cree ancestry with a history of early onset of severe bacterial, viral and fungal infections. Affected members carried a homozygous duplication in the *IKBKB* gene resulting in frameshift and premature termination, and loss of expression of IKK β (Pannicke et al., 2013). A similar SCID phenotype was described in a female infant of consanguineous parents of Turkish descent with a homozygous nonsense mutation in *IKBKB* and lack of IKK β expression (Nielsen et al., 2014).

Treatment of patients with anhidrotic ectodermal dysplasia requires a multidisciplinary approach to address the multiple and variably severe symptoms of recurrent infections, ectodermal defects, inflammation, and immune dysregulation. HSCT can be curative, but with less than optimal outcome (Pannicke et al., 2013).

Calcium channel defects

Calcium signals play a key role in the activation and effector function of lymphocytes. Calcium channel defects are autosomal recessive disorders of CA^{2+} influx from the extracellular space into lymphocytes through the calcium release-activated calcium (CRAC) channels. Mutations in genes coding for proteins that form (*ORAI1*) or control (*STIM1*) CRAC channels result in CID associated with ectodermal dysplasia, autoimmunity and congenital myopathy (Feske et al., 2006; Fuchs et al., 2012).

Mutations in the *ORAI1* or *STIM1* genes typically cause severe viral, bacterial and fungal infections due to defective TCR mediated activation resulting in impaired NFAT signaling. The numbers of T, B and NK cells are normal but in vitro lymphocyte proliferation is reduced or absent, and NK cell cytotoxicity is severely impaired. While symptomatic treatment with antimicrobials and IVIG is partially effective, HSCT to correct the immune deficiency should be considered, although HSCT does not correct myopathy nor the ectodermal dysplasia.

Purine nucleoside phosphorylase (PNP) deficiency

PNP, similar to adenosine deaminase, plays an important role in purine metabolism. Biallelic mutations in the *PNP* gene result in the intracellular accumulation of the toxic metabolite deoxyguanosine triphosphate, which inhibits DNA synthesis causing impaired lymphocyte proliferation and CID. Because PNP is an ubiquitous enzyme required by dividing cells, PNP deficient patients also suffer from non-immunological abnormalities, in particular neurologic defects such as cerebral palsy, ataxia and developmental delay (Yeates et al., 2017). Recurrent bacterial and opportunistic infections, associated with T cell lymphopenia, occur usually within the first months of life, but may be delayed to early childhood. In some cases, neurologic symptoms precede the susceptibility to infections. Autoimmunity is common and includes non-infectious arthritis, pericarditis, thyroiditis, vasculitis and cytopenias. In vitro lymphocyte proliferation in response to mitogens and antigens is reduced or absent. The defect in purine metabolism leads to reduced serum levels of uric acid, elevated deoxyguanosine in plasma and increased concentrations of d-GTP in erythrocytes. HSCT is curative and indicated early, before neurologic deficits occur (Yeates et al., 2017).

Hepatic veno-occlusive disease with immunodeficiency (VODI)

VODI is a rare syndrome with AR inheritance that presents in infancy with hepatic vein occlusion, hepatomegaly and hepatic failure, associated with hypogammaglobulinemia and clinical evidence of T cell dysfunction (Cliffe et al., 2012). Accordingly, affected infants suffer from recurrent bacterial and opportunistic (PJP, Candida, CMV) infections. While normal in number, T and B cells are mostly immature, switched memory B cells are absent and antibody responses are decreased. VODI is caused by biallelic mutations in the transcriptional regulator gene *SP110*. Treatment is symptomatic with antimicrobials, PJP prophylaxis, IgG replacement; HSCT and liver transplantation are of limited success.

Other CID disorders with syndromic features

This group of rare disorders includes monogenic defects that involve proteins with functions limited to specific organ systems.

Immunodeficiency with multiple intestinal atresia due to biallelic mutations in the *TTC7A* gene

This syndrome is often complicated by intrauterine polyhydramnios and intestinal growth restriction resulting in short bowel syndrome (Notarangelo, 2014). The combination of malabsorption, recurrent bacterial, fungal, and viral infections requires a multidisciplinary approach to manage affected patients.

Tricho-Hepato-Enteric syndrome (THES) caused by biallelic mutations in *TTC37* or *SKIVL2*

THES is characterized by facial dysmorphism, intrauterine growth retardation, wooly hair, chronic diarrhea, liver disease and skin abnormalities (Monies et al., 2015). Most patients have recurrent respiratory infections and antibody deficiency.

Neurologic deficiencies associated with CID

These syndromes include AD BCL11B deficiency with severe T cell abnormalities that may resemble SCID with low TRECs at newborn screening (Punwani et al., 2016) and biallelic mutations in *EPG5* (VICI syndrome) associated with early onset recurrent infections (Abidi et al., 2020). Both syndromes present with CNS abnormalities (absence of corpus callosum), developmental delay and cutaneous manifestations.

HOIL1 and HOIP deficiency

These deficiencies are due to biallelic mutations in *RBCK1* (HOIL1) and *RNF31* (HOIP), respectively, and are associated with hypogammaglobulinemia, lymphopenia, bacterial infections, autoinflammation and amylopectinosis. HOIL1 and HOIP are components of the linear ubiquitination chain assembly complex (LUBAC), a constituent of the NF- κ B cascade involved in the IKK complex activation (Boisson et al., 2015).

STAT5B deficiency

STAT5B deficiency is characterized by short stature due to growth hormone insensitivity, dysmorphic features, chronic pulmonary disease presenting as interstitial pneumonitis, and recurrent bacterial and viral infections. Together with other STATs, STAT5B is an important component of the IL-2 signaling pathway, which is of critical importance for lymphoid development. STAT5B plays a specific role in the transcription of the insulin-like growth factor-1 (*IGF-1*) gene. In most STAT5B deficient patients, the inheritance is AR and the protein is absent (Vidarsdottir et al., 2006), but AD inheritance with mutations resulting in a dominant negative effect has been reported (Klammt et al., 2018).

Kabuki syndrome

This syndrome is characterized by typical facial features (long palpebral fissures with eversion of the lateral lower eyelid, arched and broad eyebrows), moderate intellectual disability, growth deficiency and other developmental anomalies (Adam et al., 2019). Recurrent respiratory infections are reported by the majority of affected individuals and autoimmune complications, such as ITP and hemolytic anemia, occur in half of the patients. The inheritance is AD involving the gene *KMT2D*, often reflecting a de novo mutation, or X-linked affecting the *KDM6A* gene.

Severe reduction in all serum immunoglobulin isotypes with profoundly decreased or absent B cells, agammaglobulinemia

(BTK deficiency, μ heavy chain deficiency, $\lambda 5$ deficiency, Ig α deficiency, Ig β deficiency, BLNK deficiency, p85 deficiency, E47 transcription factor deficiency, LRRC8 deficiency, SLC39A7 (ZIP7) deficiency, p110 δ deficiency, TOP2B deficiency).

Pathogenesis

Absence of peripheral B cells with severe reduction in all serum immunoglobulin levels is the hallmark of agammaglobulinemia, a rare form of PID; X-linked, autosomal recessive and autosomal dominant forms of the disease have been described. Affected patients present with early onset of recurrent bacterial infections, typically within the first 12 months of life. The incidence of the disease varies from 1:100000 to 1:200000 depending on ethnicity and specific genetic defect involved.

The most frequent form of this group of PADs is X-linked agammaglobulinemia (XLA). XLA or BTK deficiency represents the prototype for PID and was the first immunological disorder for which the genetic cause was discovered. The first patient was described by colonel Bruton (1952), but was only in the early 1990s that two different groups described the underlying genetic defect as mutations in Bruton's tyrosine kinase (BTK, OMIM 300,300), a member of the Tec family of kinases (Tsukada et al., 1993; Vetrie et al., 1993). Early B cell development takes place in the bone marrow and is characterized by specific maturational steps starting from pro-B to pre-B to immature and then mature B cells that exit the bone marrow and enter the periphery (Conley, 2002). Pre-B cells express the pre-BCR receptor complex that requires BTK for the initiation of the downstream signaling cascade, necessary for further maturation. Mutations in BTK result in a developmental arrest of B cell development in the bone marrow at the pro-B to pre-B stage. This early block in B cell development results in less than 1% of B cells in the periphery of these patients. Immunoglobulin levels are very low for all classes and there is virtually no humoral response to recall antigens. The almost total lack of circulating B cells results in reduced size of lymph nodes and tonsils, tissues normally highly populated by B cells. On the other hand, both number and function of T cells are conserved, with the former being slightly increased.

BTK maps on the X-chromosome and mutations can be both familial and de novo ones; in the first case, mothers of affected individuals are healthy carriers.

Agammaglobulinemia with autosomal recessive transmission (autosomal recessive agammaglobulinemia; ARA) is even more rare than XLA. ARA affects both males and females and is characterized by severe reduction of all serum immunoglobulin classes and absence of peripheral B cells, in the absence of BTK mutations. The underlying genetic defect has been identified only in a limited number of patients. As stated earlier, early B cell development in the bone marrow depends on the sequential expression of specific gene products that promote B cell differentiation from the pro-B to pre-B, then to immature B and to mature B cell that enters the periphery (Conley, 2002). Pre-B cells express the pre-BCR, a receptor complex formed by the μ (mu) heavy chain, Ig α , Ig β , VpreB and λ 5. The pre-BCR complex is essential for the initiation of downstream signaling essential for B cell differentiation, which in turn depends on kinases such as BTK (Martensson et al., 2007). In fact, mutations in the μ heavy chain (IGHM, OMIM*147020), Ig α (CD79A, OMIM*112205), Ig β (CD79B, OMIM*147245), λ 5 (IGLL1, OMIM*146770), B-cell linker protein (BLNK, OMIM*604515), p85 α (PIK3R1, OMIM*171833) genes have been identified in a limited number of patients affected with ARA (Yel et al., 1996; Minegishi et al., 1998, 1999; Wang et al., 2002; Dobbs et al., 2007; Ferrari et al., 2007a,b; Conley et al., 2012).

Clinical manifestations

Clinical symptoms in affected patients initiate typically between the ages of 6–12 months, when the maternal IgGs are catabolized. Nonetheless, a minority of patients may remain asymptomatic for the first year of life. Recurrent bacterial respiratory and/or gastrointestinal infections are the hallmark of this disorder.

XLA and clinical manifestations

XLA patients suffer from recurrent otitis media, sinusitis, bronchitis, pneumonia, skin and gastrointestinal infections (Plebani et al., 2002; Aghamohammadi et al., 2006a,b; Winkelstein et al., 2006; Lougaris et al., 2020) mainly sustained by encapsulated pyogenic bacteria, namely *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Staphylococcus aureus* and others. *Pseudomonas* species has been reported to be the most frequently isolated pathogen in septicemia, followed by *H. influenzae*, *S. pneumoniae* and *S. aureus*. Septic arthritis in these patients is mainly caused by *H. influenzae* and *S. pneumoniae* before intravenous immunoglobulin (IVIG) therapy, whereas a viral cause is considered responsible upon initiation of IVIG therapy. Bacterial meningitis can also complicate the history of these patients, especially before Ig replacement treatment is initiated (Plebani et al., 2002; Winkelstein et al., 2006; Aghamohammadi et al., 2006a,b; Lougaris et al., 2020).

Typically, XLA patients suffer from recurrent infections of the upper and lower respiratory tract. Chronic sinusitis is present in more than 65% of patients. Recurrent bronchitis and/or pneumonia continue to occur even when regular IVIG therapy has been established, leading to the development of bronchiectasis in almost 47% of patients after 40 years of follow-up, in the presence of chronic sinusitis in the majority of cases (84%) (Lougaris et al., 2020).

Besides bacterial infections, viral infections may complicate the natural history of XLA. Affected patients are particularly susceptible to enteroviruses, namely poliovirus, echovirus and coxsackie virus. Vaccine associated poliomyelitis after live-attenuated oral vaccine (Sabin) has been reported and is complicated by a high mortality rate. Enteroviral meningoencephalitis in XLA patients tends to manifest slowly over the years, although fulminating infection with fever, headache and seizures has also been reported (Bearden et al., 2016). Unfortunately, isolation of the viral pathogen is very difficult, and the lack of an isolate cannot exclude the infection in XLA patients. High dose IVIG treatment has been shown to be efficient in controlling the infection and limiting the CNS (central nervous system) involvement, however, the limited number of patients studied does not allow statistical conclusions. Chronic enteroviral infection eventually results in cerebral edema, diffuse inflammation and progressive cerebral atrophy (Misbah et al., 1992; Bearden et al., 2016).

Arthritis has been reported in almost 20% of XLA patients (Plebani et al., 2002; Winkelstein et al., 2006; Aghamohammadi et al., 2006a,b; Lougaris et al., 2020). Clinical findings are indistinguishable from classical Rheumatoid Arthritis (RA), including motion limitation, effusion, pain and destructive pannus formation. Although no isolates are found in the majority of cases, these manifestations tend to respond to IVIG therapy, suggesting a potential infectious cause. Antibiotics are usually associated with the IVIG treatment. In many reported cases, an enteroviral or mycoplasma infection was associated with the rheumatic manifestations.

Neutropenia has also been reported in XLA in a percentage that is variable from 10–25% (Aghamohammadi et al., 2006a,b; Winkelstein et al., 2006), although the clear involvement of BTK in neutrophil development has not yet been elucidated.

ARA and clinical manifestations

Clinical symptoms in patients with μ heavy chain deficiency are similar to those observed in XLA, although frequently in a more severe presentation and at an earlier age (Yel et al., 1996; Minegishi et al., 1998, 1999; Wang et al., 2002; Dobbs et al., 2007; Ferrari et al., 2007a,b; Conley et al., 2012). In fact, age at diagnosis also appears younger for this disorder when compared to XLA. Chronic enteroviral encephalitis, recurrent bronchitis, pneumonia, *Pseudomonas aeruginosa* sepsis, otitis media and other symptoms characterize the onset of the disease. The clinical history ameliorates after immunoglobulin replacement therapy is initiated at a regular basis. Neutropenia has also been reported in almost a third of patients with this disorder.

The clinical history of the first patient affected with λ 5 deficiency started at the age of 2 months with recurrent otitis media; he was found to be hypogammaglobulinemic with absence of peripheral B cells at the age of 5 years, when he was hospitalized for *Haemophilus meningitis*. Bone marrow studies showed a specific block at the pro-B to pre-B cell stage of differentiation (Minegishi et al., 1998).

The first female patient affected with Ig α deficiency presented with chronic diarrhea and failure to thrive within the first month of life (Wang et al., 2002). At 1 year of age, she was hospitalized for bronchitis and neutropenia. Immunological work-up showed severely reduced levels of all immunoglobulin classes and absence of peripheral B cells. Bone marrow analysis evidenced a specific block at the transition from pro-B to pre-B cell no lymph nodes were detectable during clinical examination. The second patient was a male with a history of respiratory infections, diarrhea and a dermatomyositis-like picture who died of a pulmonary infection.

The patient with the hypomorphic mutation in Ig β presented with recurrent lower respiratory tract infections at the age of 5 months (Dobbs et al., 2007). After initiation of IVIG therapy at the age of 15 months, her clinical symptoms improved significantly. The patient carrying a non-sense mutation in the Ig β gene was first admitted at the age of 8 months for pneumonia and Salmonella-caused enteritis (Ferrari et al., 2007a); his immunological workup revealed a complete absence of peripheral B cells (CD19 <1%) and pan-hypogammaglobulinemia. When IVIG therapy was initiated, the patient's clinical history was complicated by recurrent bronchitis, sinusitis, otitis media and bacterial conjunctivitis.

The first reported patient with BLNK deficiency (Minegishi et al., 1999), suffered from recurrent otitis since the age of 8 months and reported two episodes of pneumonia before the age of 6 months. The first immunological workup revealed undetectable serum IgG, IgA and IgM levels in the absence of peripheral B cells. Once on regular IVIG therapy and during an 18-year period of follow-up, his clinical history was complicated by chronic otitis and sinusitis, hepatitis C secondary to contaminated immunoglobulin preparation, and protein-losing enteropathy.

The single female patient affected with p85a deficiency due to a premature stop codon suffered from colitis without particular infectious history. Peripheral B cells were absent with an early block in bone marrow B cell development (Conley et al., 2012).

The condition of agammaglobulinemia with absent B-cells may be observed in other conditions beside the ones described so far. E47/TCF3 deficiency was found in four patients with agammaglobulinemia and reduced peripheral B cells that expressed CD19 but lacked BCR expression on the cell surface. The leucine-rich repeat-containing 8 (LRRC8), another gene implicated in the pathogenesis of agammaglobulinemia, was identified to be mutated in a female patient with agammaglobulinemia and dysmorphic features (Sawada et al., 2003). Recently, the condition of agammaglobulinemia was associated with biallelic mutations in SLC39A7 encoding ZIP7, a Zn transporter, in six patients (Anzilotti et al., 2019). All patients presented with early onset infections, agammaglobulinemia and absence of circulating B cells (CD19 B cells: <1%). Two of them, due to co-morbidities, underwent HSCT with positive outcome. A single patient with autosomal recessive deficiency of p110delta and agammaglobulinemia complicated with autoimmune thrombocytopenia and enterocolitis was recently described (Swan et al., 2019). Patients with autosomal dominant mutations in TOP2B and agammaglobulinemia have also been reported (Broderick et al., 2019).

Diagnosis

The typical laboratory findings of agammaglobulinemia consist of low to undetectable immunoglobulin serum levels and the almost complete absence of peripheral B cells (<2% of lymphocytes), reflecting the early block in B cell development. However, rare cases of patients with peripheral B cells and/or near normal Ig levels have been reported. In such cases, antibody responses to vaccines were abnormal and this may be used for further characterization. T cell numbers and function are typically normal, although the former may be slightly elevated. Once the clinical suspicion is supported by laboratory findings, molecular analysis of the BTK gene should be performed in male patients in order to identify the mutation. If the molecular analysis is not available, evaluation of the expression of BTK protein by means of flow cytometry in monocytes, is an alternative valuable and a rapid diagnostic tool. If the protein is not expressed a definite diagnosis of XLA is made, and genetic analysis can be done subsequently in order to define the causative mutation. Cytofluorimetric analysis of BTK expression can also be used for carrier detection. Once the mutation is defined, carrier diagnosis and prenatal diagnosis can also be performed. If mutation analysis for BTK is negative or if the patient is female, genetic analysis for the above-mentioned genes should be undertaken.

Treatment and prognosis

Immunoglobulin replacement treatment (IgRT), intravenous or subcutaneous is the first line treatment for all patients affected with agammaglobulinemia of any type. Every acute bacterial infectious episode should be treated with antibiotics. In some cases, antibiotic prophylaxis may be necessary, depending on the type and number of infectious episodes. The most recent longitudinal study of 168 XLA patients showed that, independently of IgRT, affected patients show reduced overall survival at 40 years of age which is further reduced in the presence of bronchiectasis (Lougari et al., 2020). These data suggest that current treatment strategies are not sufficient to prevent these complications and to guarantee a normal survival for affected patients.

Adverse reactions to immunoglobulin administration should be monitored during therapy. The most common reactions include nausea, vomiting, chills, low-grade fever, myalgia and fatigue. Adverse effects may occur within 30 min from infusion and usually last for several hours. Slowing the rate of infusion or interrupting the infusion for a few minutes greatly helps in preventing symptoms. These reactions may be minimized by pre-medication with anti-inflammatory drugs including corticosteroids.

Severe reduction in at least 2 serum immunoglobulin isotypes with normal or low number of B cells, CVID phenotype

(ICAROS deficiency, TACI deficiency, BAFFR deficiency, CD19 deficiency, CD20 deficiency, D81 deficiency, CD21 deficiency, PRKCD deficiency, p110 δ deficiency, p85 α deficiency, TWEAK deficiency, LRBA deficiency, NFKB2 deficiency, NFKB1 deficiency, CTLA-4 deficiency, PTEN deficiency, TRNT1 deficiency, IRF2BP2 deficiency, ATP6AP1 deficiency, ARHGEF1 deficiency, SH3KBP1 deficiency, SEC61A1 deficiency, RAC2 deficiency, MOGS deficiency).

Pathogenesis

Hypogammaglobulinemia with normal or low number of B-cells represents a group of PADs of which common variable immunodeficiency (CVID) is the prototype. CVID is a heterogeneous group of disorders, characterized by hypogammaglobulinemia, defective specific antibody production, increased susceptibility to recurrent and chronic infections (Aghamohammadi et al., 2005; Cunningham-Rundles and Bodian, 1999) and an increased incidence of autoimmune disorders and cancers (Cunningham-Rundles et al., 1987; Knight and Cunningham-Rundles, 2006).

CVID has an estimated prevalence ranging from 1:10,000 to 1:50,000 (Darragh, 1982; Fasth, 1982; Hammarstrom et al., 2000) with equal distribution between males and females. It may present at any age but the peak of presentation occurs in early adult life (Luzi et al., 1983; Notarangelo et al., 2004) with an average period of 5–6 years between the onset of symptoms and diagnosis (Aghamohammadi et al., 2005; Cunningham-Rundles and Bodian, 1999).

Diagnosis of CVID is based on a decrease of immunoglobulins of at least two isotypes (serum IgG, IgA, and/or IgM) by two or more standard deviations from the normal mean for age and genetic exclusion of other antibody deficiencies associated with well-defined single gene defects.

Although most CVID cases are sporadic, it has been estimated that 10–20% are familial, mostly with autosomal dominant inheritance (Ashman et al., 1992; Hammarstrom et al., 2000; Nijenhuis et al., 2001). In multiple-case families, CVID is often present in one parent, accompanied by IgA deficiency (IgAD) in the descendants (Vorechovsky et al., 1999) and it has been estimated that about 15% of the patients with CVID have a first degree relative with either IgAD or CVID (Burrows and Cooper, 1997; Vorechovsky et al., 1995). Attempts to identify the genes responsible for CVID have resulted in finding several monogenic defects.

The first genetic defect leading to CVID was identified in inherited homozygous deletions in the *ICOS* gene (*ICOS*, OMIM*604558) in 4 adult-onset CVID patients (Grimbacher et al., 2003). T cells from these individuals were normal with regard to subset distribution, activation, cytokine production and proliferation. In contrast, naive, switched and memory B cells were reduced. The phenotype of human *ICOS* deficiency, which differs in key aspects from that of the *Icos*^{-/-} mice, suggests a critical involvement of *ICOS* in T cell help for late B cell differentiation, class-switching and memory B cell generation. Following the description of mutations in TACI and BAFFR, that are associated or causative of CVID (Salzer et al., 2004; Salzer et al., 2009; Warnatz et al., 2009; Pieper et al., 2014; Losi et al., 2005; Lougaris et al., 2016). CD19 deficiency (OMIM#107265) was identified in four patients (van Zelm et al., 2006). Three patients carried the homozygous deletion 1384del(GA), while one harboured the homozygous insertion 972ins(A), both causing a premature stop codon leading to lack of CD19 expression by B cells. CD27⁺ memory B cells were decreased in affected patients. BCR cross-linking failed to induce a vigorous B cell activation and recall response to vaccinations was poor (van Zelm et al., 2006). Another patient with CD19 deficiency was identified after the initial description, carrying a compound heterozygous mutation (Kanegane et al., 2007). Mutation analysis of *CD19* in this patient revealed a mutation in the splice acceptor site of intron 5 (IVS5-1G >T) of the maternal allele, resulting in skipping of exon 6, and thus a truncated protein product. The paternal allele was disrupted by a gross deletion encompassing at least the *ATP2A1*, *CD19* and *NFATC2IP* genes (Kanegane et al., 2007).

After the description of CD19 deficiency, CD20 deficiency was identified due to a homozygous splice site mutation in the *CD20* gene in a single patient with hypogammaglobulinemia. The patient showed defective antibody formation upon T-independent antigen stimulation, similarly to what has been observed in *cd20* knockout mice (Kuijpers et al., 2010).

Lack of CD19 expression by B cells was described in a patient with hypogammaglobulinemia and severe nephropathy (van Zelm et al., 2010). However, the lack of CD19 was not due to CD19 deficiency but to CD81 deficiency, a member of the tetraspanin family that interacts with CD19 and CD21 on the B cell surface. Genetic analysis showed a homozygous c.561 + 1G >A mutation in the *CD81* gene leading to a complete lack of CD81 expression. Memory B cells were reduced in this patient as well. As observed in CD19 deficiency, BCR cross-linking failed to activate properly B cells; in contrast, T cell activation was conserved (van Zelm et al., 2010).

Immunological evaluation of an adult patient with recurrent infections and hypogammaglobulinemia demonstrated lack of CD21 expression by B cells (Thiel et al., 2012). Sequence analysis revealed a compound heterozygous deleterious mutation in the *CR2* gene (encoding CD21) (c.1225 + 1G >C/W766X). Class-switched memory B cells were reduced. While vaccination responses to protein antigens were normal, the response to pneumococcal polysaccharide vaccination was impaired (Thiel et al., 2012).

The genetic defects described so far as associated or causative of CVID are related to receptors expressed on the cell surface. Genetic defects affecting cytoplasmic proteins were subsequently reported in patients with clinical and immunological phenotypes compatible with CVID. Salzer et al. (2013) reported a single patient from a consanguineous family, with progressive B cell lymphopenia, hypogammaglobulinemia and severe autoimmunity, who was affected with PRKCD deficiency due to a homozygous

(c.1352 + 1G >A) splice site mutation leading to absent protein expression. PRKCD deficiency due to a R614W homozygous mutation was reported in a single patient with chronic, low-grade Epstein-Barr virus infection (Kuehn et al., 2013). The patient had chronic lymphadenopathy, splenomegaly, autoantibodies, hypergammaglobulinemia and natural killer cell dysfunction. A homozygous mutation in PRKCD (p.G510S) was identified in three patients affected with systemic lupus erythematosus, who also showed B cell defective apoptosis and hyperproliferation (Belot et al., 2013).

Dominant-activating germline mutations in the gene encoding the PI(3)K catalytic subunit p110 δ were identified in patients with a CVID-like phenotype (APDS-1; Activated phosphoinositide 3-kinase δ syndrome) (Angulo et al., 2013; Lucas et al., 2014a,b). Affected patients presented with variable features, including lymphopenia, hypogammaglobulinemia, variable B and T cell maturational defects and, of note, T cell senescence. A comprehensive study of a large cohort of affected patients revealed an increased prevalence of B-cell lymphomas in patients affected with APDS-1 (Kracker et al., 2014).

Besides the identification of dominant mutations in the p110 δ catalytic subunit of PI3K, monoallelic mutations in PIK3R1, the gene encoding for the regulatory subunit p85 α of PI3K, were also identified (Deau et al., 2014; Lucas et al., 2014a,b; Lougaris et al., 2015a,b), causing APDS-2. Affected patients present with recurrent respiratory infections, gut involvement, enlarged lymph nodes and tonsils, normal to elevated IgM serum levels, low IgG and IgA, and variable lymphopenia. NK cell evaluation in patients with APDS-1 and APDS-2 revealed important functional NK cell defects (Lougaris et al., 2016; Ruiz-Garcia et al., 2018).

Considering that in APDS, both type 1 and 2, the genetic defect leads to hyperactivation of the PI3K pathway, and thus of mTOR and AKT, targeted inhibition of this cascade, for example with rapamycin, an mTOR inhibitor, or specific PI3K inhibitors, may become an effective strategy for the treatment of affected patients (Angulo et al., 2013; Lucas et al., 2014a,b; Deau et al., 2014).

TWEAK deficiency was identified in a single family with three affected members (father, daughter and son). All patients showed variable antibody deficiency, recurrent infections and defective vaccine responses (Wang et al., 2013). They carried a rare mutation in the sixth exon of TWEAK, p.R145C, within the conserved TNF-homology domain of the full-length protein. Functional in vitro experiments showed that the mutant protein caused inhibition of BAFF-dependent B-cell survival and proliferation, suggesting a causative pathogenetic role of this mutant for the CVID phenotype in this family (Wang et al., 2013).

LRBA (lipopolysaccharide responsive beige-like anchor protein) deficiency was described in patients with CVID and/or autoimmune disorders (Lopez-Herrera et al., 2012; Burns et al., 2012). Lopez-Herrera et al. identified five CVID patients harboring homozygous mutations (I2657S, R1683X, E59X and a large deletion that includes exons 1 and 2) in the gene encoding for LRBA causing loss of protein expression. All patients had early onset hypogammaglobulinemia and severe autoimmune manifestations. Immunological evaluation revealed disturbed B cell development, abnormal in vitro B cell activation, immunoglobulin secretion and proliferation, and defective B cell autophagy. LRBA deficiency due to a large homozygous deletion including exons 1 to 30 was recently reported in a single patient with autoimmunity but without hypogammaglobulinemia, suggesting that LRBA defects may present with variable immunological phenotypes (Burns et al., 2012). Considering the complicated clinical course of LRBA deficiency, based on long-term follow-up of numerous affected patients (Gamez-Diaz et al., 2016), HSCT has been implemented in a small number of cases, with variable results (Gamez-Diaz et al., 2016; Backthiar et al., 2017). Since LRBA deficiency leads to lack of CTLA-4 expression by T regulatory cells, Abatacept has become a promising therapeutic option (Lo et al., 2015; Alroqi et al., 2017).

Alterations in components of the NF- κ B pathway were recently associated with the pathogenesis of CVID. Germline mutations in NFKB2, a component of the non-canonical NF- κ B pathway, were described in a small number of patients affected with early onset hypogammaglobulinemia, recurrent infections, autoimmune features and adrenal insufficiency (Chen et al., 2013). These NFKB2 mutations cause altered processing of p100 and affect p52 nuclear translocation. Upon the initial description of NFKB2 deficiency, additional CVID patients with NFKB2 mutations have been described (Lindsley et al., 2014; Lee et al., 2014; Lougaris et al., 2015a,b). Of interest, evaluation of NK cells from affected patients revealed defective cytotoxic activity, a rather unusual feature for CVID (Lougaris et al., 2015a,b).

Monoallelic mutations in NFKB1, a component of the canonical NF- κ B pathway, were recently identified in adult-onset CVID patients that presented with hypogammaglobulinemia, recurrent infections and variable autoimmune features (Fliegauf et al., 2015). The identified mutations altered the normal processing of p105 and the nuclear localization of p50 (Fliegauf et al., 2015). Evaluation of B cell maturation showed both early and late B cell developmental alterations in NFKB1 mutated patients (Lougaris et al., 2016a). Following the identification of this genetic defect, additional cases have been described, broadening the clinical and immunological phenotype (Schippe et al., 2016; Boztug et al., 2016). Of interest, as observed in NFKB2 deficiency, NK cell evaluation in affected patients revealed functional and developmental abnormalities (Lougaris et al., 2016b).

Monoallelic mutations in Cytotoxic T lymphocyte antigen 4 (CTLA-4) were identified as responsible for a complex CVID-like condition (Schubert et al., 2014; Kuehn et al., 2014). CTLA-4 is expressed in regulatory T cells upon activation and exhibits an inhibitory function on T cell biology. Affected patients present a complex syndrome of immune dysregulation and may present with hypogammaglobulinemia, lymphopenia, autoimmune cytopenia, lymphoproliferation and granuloma formation, resembling LRBA deficiency (Lopez-Herrera et al., 2012; Gamez-Diaz et al., 2016). Of note, affected patients seem to present an increased risk of gastric cancer, which has been experimentally confirmed in animal models (Miska et al., 2018). Considering the available experience with the biology of CTLA-4, targeted treatments with CTLA-4-Ig may become a promising tool in the treatment of patients affected with CTLA-4 or LRBA deficiency, since LRBA regulates CTLA-4 expression (Lo et al., 2015; Alroqi et al., 2017).

An immunological phenotype compatible with CVID may be observed in a number of additional genetic defects.

Autosomal-dominant germline mutations in *PTEN* have been reported in patients with hypogammaglobulinemia associated with reduced CD27⁺ memory B cells, and normal naive, memory, and effector CD4 and CD8 T cells (Driessen et al., 2016). Biallelic

mutations in *TRNT1* lead to defective mitochondrial translation and cause a phenotype referred to as congenital sideroblastic anemia with immune deficiency, fevers and developmental delay (SIFD). Patients typically have hypogammaglobulinemia with poor maturation of B cells (Wiseman et al., 2013). Heterozygous germline *IKZF1* mutations have been identified in patients with a B cell immunodeficiency mimicking CVID (IKAROS deficiency). These mutations demonstrated incomplete penetrance leading to haploinsufficiency (Kuehn et al., 2016). Autosomal dominant mutations in the *IRF2BP* gene have been reported in a small number of patients with a CVID-like phenotype, combining hypogammaglobulinemia with colitis (Keller et al., 2016). ATP6AP1 deficiency has been observed in a complex form of CVID associated with liver damage and neurological involvement (Jansen et al., 2016). Compound heterozygous mutations in *ARHGEF1*, resulting in the loss of ARHGEF1 protein expression were recently identified in 2 antibody-deficient siblings presenting with recurrent severe respiratory tract infections and bronchiectasis (Bouafia et al., 2019). Patients harboring a germline deletion within the *SH3KBP1/CIN85* gene on the X chromosome show primary antibody deficiency with B lymphocyte intrinsic defects in distinct effector pathways of the B cell antigen receptor, most notably NF- κ B activation and up-regulation of CD86 expression on the cell surface (Keller et al., 2018). Patients with hypogammaglobulinemia and heterozygous mutations in the *SEC61A1* gene show defective plasma cell differentiation (Schubert et al., 2018). While monoallelic dominant negative mutations in *RAC2* result in neutrophil defects, monoallelic germline activating mutations result in hypogammaglobulinemia with lymphocyte defects compatible with a combined immunodeficiency. To date only two siblings born to consanguineous parents presented with a CVID-like phenotype due to homozygous deficiency of *RAC2* (Lougaris et al., 2020). Mutations in the gene encoding MOGS (also known as glucosidase 1) cause severe hypogammaglobulinemia with susceptibility to viral infections, often associated with neurological involvement (Sadat et al., 2014).

Clinical manifestations

The main clinical symptoms associated with CVID patients are recurrent infections, autoimmune manifestations, and an increased incidence of lymphoma and other selected cancers. The age at onset of symptoms is variable, ranging from childhood to late adult life, with some evidence of a bimodal distribution, demonstrating two peaks between 1 and 5 years and also 18 and 25 years (Aghamohammadi et al., 2005; Cunningham-Rundles and Bodian, 1999). In contrast to patients with XLA, patients with CVID have normal sized or enlarged tonsils and lymph nodes and approximately 25% of patients develop splenomegaly (Holm et al., 2005).

Almost all patients with CVID have a history of acute, chronic, or recurrent infections, particularly pneumonia, sinusitis and otitis (Aghamohammadi et al., 2005; Cunningham-Rundles and Bodian, 1999; Hermaszewski and Webster, 1993). Approximately 89% of patients with CVID have had at least one episode of chronic sinusitis and 70% have had recurrent otitis media before establishing the diagnosis (Aghamohammadi et al., 2007; Martinez Garcia et al., 2001). Between 75% and 84% of CVID patients have experienced at least one episode of pneumonia before diagnosis, and many have suffered multiple episodes (Busse et al., 2002; Pourpak et al., 2006; Sweinberg et al., 1991). Bronchiectasis, an irreversible lung complication, has been reported in a variable percentage (37.5–73%) of CVID patients (Kainulainen et al., 1999; Park et al., 2005; Thickett et al., 2002). It has been documented that subgroup of CVID patients who have low numbers of IgM memory B cells and reduced levels of anti-pneumococcal polysaccharide IgM antibodies are at an increased risk of developing recurrent bacterial pneumonia and bronchiectasis. Measurement of these parameters may be useful for the attending physicians and may result in more aggressive and targeted treatment strategies. Asthma represents an obstructive lung complication, which has been observed in 9–15% of patients with CVID (Mullighan et al., 1997). The etiology of asthma in patients with CVID is unknown.

Non-caseating, granulomatous infiltrations have been reported in less than 25% of patients with CVID (Fasano et al., 1996; Mechanic et al., 1997). These lesions are not clearly distinguishable from sarcoidosis. Non-caseating granulomas are occasionally also found in lymphoid tissues or the liver (Mechanic et al., 1997).

Lymphoid interstitial pneumonitis (LIP) may develop in the lower airways of patients with CVID (Buckley, 2004; Davies et al., 2000). LIP can be suspected based on findings on high resolution CT (HRCT) scan. Presence of granulomatous lung disease and/or LIP are associated with a worse prognosis and higher rate of lymphoproliferative disease (Bates et al., 2004; Koss et al., 1987). There is a high prevalence of inflammatory and infectious gastrointestinal disorders in patients with CVID (Washington et al., 1996). Mild, watery diarrhea is common and occurs periodically in about 20% of patients, with 10% having a more severe enteropathy resulting in malabsorption and weight loss (Teahon et al., 1994). Gastrointestinal pathology in these patients includes nodular lymphoid hyperplasia, inflammatory bowel disease (ulcerative colitis, ulcerative proctitis, or Crohn's disease), sprue-like illness with flat villi, chronic giardiasis and nonspecific malabsorption. Defects in cellular immunity, rather than antibody deficiency alone, appear to predispose patients to such symptoms (Washington et al., 1996). *Helicobacter pylori* is an important pathogen in CVID resulting in chronic active gastritis involving both antrum and corpus.

Approximately 10% of CVID patients have significant liver dysfunction, due to hepatitis B and C virus infection, primary biliary cirrhosis, and granulomatous disease.

Approximately one fourth of patients with CVID have, at the time of diagnosis or later, developed one or more autoimmune conditions such as autoimmune hemolytic anemia, thrombocytopenia, rheumatoid arthritis, or pernicious anemia (Aukrust et al., 1996; Cunningham-Rundles et al., 1991; Hermaszewski and Webster, 1993).

While there is an increased susceptibility to autoimmunity, the mechanism underlying this complication is unknown. Most CVID patients with idiopathic thrombocytopenia purpura (ITP) or autoimmune hemolytic anemia have been successfully treated with infusions of high doses of intravenous immunoglobulin (IVIG), coupled with a short course of corticosteroids. However, due to a higher incidence of medical complications associated with the use of immunosuppressive drugs in patients with CVID, this type of therapy should be used with caution (Cunningham-Rundles et al., 1991).

Individuals with CVID are susceptible to malignancy, particularly lymphoma. The incidence of malignancy is increased (11–13%) in CVID during the fifth and sixth decades of life (Hermaszewski and Webster, 1993). The majority of these malignancies involve the gastrointestinal tract and lymphoid tissues (Cunningham-Rundles et al., 1991; Filipovich et al., 1994; Kinlen et al., 1985; Kokron et al., 2004; Mellemkjaer et al., 2002; Sander et al., 1992). An association between Non-Hodgkin Lymphoma (NHL) and congenital immunodeficiency is well established, and most of the NHL cases associated with immunodeficiency appear in patients with T cell defects. In a survey of malignancy in CVID patients, a 438-fold increased likelihood of developing NHL was reported for females compared to the age-adjusted expected incidence in normal controls (Cunningham-Rundles et al., 1987). A 1.8 to 5-fold increase in all types of cancers has been described in CVID patients, with a 47-fold increase for stomach cancer and a 30-fold increase for lymphoma. Benign manifestations of lymphoproliferation, including nodular lymphoid hyperplasia, splenomegaly and generalized lymphadenopathy, have also been reported (Kinlen et al., 1985; Kokron et al., 2004; Pulvirenti et al., 2018).

Mucosa-associated lymphoid tissue (MALT) lymphoma, which represents a subset of low-grade B-cell non-Hodgkin lymphomas, is a rare complication in CVID patients (Aghamohammadi et al., 2006a,b; Reichenberger et al., 2001).

Diagnosis

The most important laboratory criterion for establishing the diagnosis of CVID is a low serum IgG concentration, ranging from profoundly reduced (<100 mg/dl) to just 2 SDs below the normal values for age (International Union of Immunological Societies, 1999; Conley et al., 1999). Most patients have low levels of IgA, and approximately half show reduced IgM levels. Documenting impaired production of specific antibodies (isohemagglutinins and/or poor responses to one or more vaccines) is part of the diagnostic work-up for CVID.

Flow cytometry is important in evaluating numbers of peripheral B cells in patients with profound hypogammaglobulinemia. Numbers of B cells in the peripheral blood may be normal or reduced and approximately 13% of patients will have a B-cell count of less than 3% in peripheral blood (Cunningham-Rundles and Bodian, 1999). Approximately half of the patients with CVID have reduced T-cell numbers and diminished lymphocyte proliferative responses to mitogens and antigens.

As there is no single diagnostic immunological or genetic test for CVID, it is important that patients are investigated to exclude other well-defined causes of hypogammaglobulinemia.

Treatment and prognosis

The mainstay of treatment for CVID is immunoglobulin replacement therapy (IgRT) (Buckley and Schiff, 1991; Ochs et al., 1986; Orange et al., 2006). Intravenous (IVIG) (Orange et al., 2006) or subcutaneous (SCIG) (Fasth and Nystrom, 2007; Ochs et al., 2006) IgRT can be used on a regular basis to maintain a trough level of at least 400–500 mg/dl. A dose of 400–600 mg/kg every 3–4 weeks is usually required. It has been shown that doses of 600 mg/kg every 4 weeks achieved serum IgG trough levels of greater than 500 mg/dl (Roifman et al., 1987). In patients with structural lung damage, a trough level of 700–800 mg/dl is required. Higher doses of immunoglobulin may be necessary for patients with severe chronic sino-pulmonary infections and to prevent bronchiectasis (Quartier et al., 1999).

Adverse reactions to immunoglobulin administration should be monitored during therapy. The most common reactions include nausea, vomiting, chills, low-grade fever, myalgias and fatigue. Adverse effects may occur within 30 min from starting the infusion and usually last for several hours. Slowing the rate of infusion or interrupting the infusion for a few minutes greatly helps in preventing symptoms. These reactions may be minimized by pre-medication with anti-inflammatory drugs including corticosteroids.

In addition to IVIG or SCIG, other forms of supportive care, such as the use of prophylactic antibiotics and lung physiotherapy, are important as bacterial infections may continue, albeit at a reduced rate, even with appropriate immunoglobulin replacement (Busse et al., 2002; Cunningham-Rundles and Bodian, 1999).

Treatment options may become more “tailored” in some cases, as described above for APDS-1 and -2 (rapamycin, p110 inhibitors) or for CTLA-4 and LRBA deficiency (Abatacept).

The prognosis for patients with CVID depends on the frequency of infections, extent of structural lung damage and concomitant presence of autoimmune disease. Other major factors in determining the prognosis are the extent of end-organ damage and the success of prophylaxis against infections. Patients and their families should be educated about early signs of infection in order not to delay treatment.

Severe reduction in serum IgG and IgA with normal/elevated IgM and normal numbers of B cells

(autosomal hyper IgM) (AID deficiency, UNG deficiency, INO80 deficiency, MSH6 deficiency, Other CSR selective deficiency).

Pathogenesis

These types of Hyper IgM (HIGM) syndromes are a consequence of defect in the class switch recombination (CSR) machinery (Durandy et al., 1997) and are currently termed Ig-CSR deficiency. Defect in these syndromes is selectively an intrinsic and pure B-cell defect, caused by mutations in Activation-Induced Cytidine Deaminase (*AICDA* or AID, OMIM*605257), Uracyl-DNA

Glycosylase (*UNG*, OMIM*191525) and others undefined genes (Durandy et al., 2004; Imai et al., 2003a; Imai et al., 2003b; Quartier et al., 2004). These disorders are clinically characterized by low or absent IgG, IgA and IgE levels, normal or elevated IgM, recurrent and chronic bacterial (not opportunistic) infections, lymphoid hyperplasia and autoimmune disorders (Durandy et al., 1997). In contrast to HIGM due to defects in CD40-mediated signaling (CD40 ligand and CD40), they have a better prognosis (Korthauer et al., 1993; Nonoyama et al., 1993).

The maturation of the antibody repertoire produces several antibody isotypes with high affinity for antigen, which is an important and basic component of humoral immunity. The maturation of the antibody repertoires takes place in primary (fetal liver and bone marrow) and secondary (lymph nodes, tonsils, and spleen) lymphoid organs. In primary lymphoid organs B-cell undergo the DNA recombination event. At this stage, the process of V(D)J and VJ recombination, which is antigen and T cell independent, results in the expression of surface immunoglobulins (IgM and IgD) on B cells.

Once surface IgM positive B cells are generated in the bone marrow, they migrate to the secondary lymphoid organs. Such as spleen, lymph nodes, where they may encounter antigens that bind to their receptor (Manis et al., 2002). In secondary lymphoid organs, mature B lymphocytes can be stimulated to undergo second DNA modifications. During this specific activation process, two distinct antigen independent events can take place in B cells including class switch recombination (CSR) and somatic hypermutation (SHM) (Chaudhuri and Alt, 2004; Dudley et al., 2005).

Occurrence of CSR and SHM requires three successive steps including transcription of target DNA sequences, DNA cleavage and DNA repair. As result of this transcriptional step, RNA/DNA hybrids are formed on the template DNA strand, leaving the non-template DNA strand accessible to cleavage (Chaudhuri et al., 2003; Petersen et al., 2001; Ramiro et al., 2003; Yu et al., 2003). During cleavage of DNA, different components are necessary for the generation of double stranded DNA breaks (DSBs). *AID* (Catalan et al., 2003; Petersen et al., 2001) and *UNG* (Di Noia and Neuberger, 2002; Rada et al., 2002) are B-cell components required to generate DSBs. Deamination of deoxy-cytidine to deoxy-uracil and then removal of uracil on single-stranded DNA by *AID* and *UNG* respectively are an important step for the base-excision repair pathway leading to the generation of DSBs.

Defect in function of the AID protein, caused by recessive mutations in the *AID* gene, results in Ig-CSR deficiency type 1 (Durandy et al., 2006). In AID deficiency, defect in Ig-CSR leads to absence or very low levels of IgG, IgA, and IgE associated with normal or elevated serum IgM levels (Durandy et al., 2006). In affected individuals, antibody responses are restricted to the IgM isotype, without change in affinity after repeating immunization (Durandy et al., 2005; Notarangelo et al., 2006, 2007). B cells are unable to undergo CSR when activated by CD40 agonists plus cytokines.

Mutations in the gene encoding *UNG* results in profound impairment in CSR (Ig-CSR deficiency type 2) (Imai et al., 2003a,b; Lee et al., 2005). B cells are unable to undergo CSR when activated by CD40 agonists plus cytokines. *UNG* deficiency is inherited as autosomal recessive.

More than half of the HIGM patients due to intrinsic B-cell defects are not secondary to either AID or *UNG* deficiency and the molecular basis remains unknown (Durandy et al., 2004; Imai et al., 2003a,b). Similar to AID or *UNG* deficiency, B cells from these patients are not able to undergo CSR after activation by CD40 agonists and cytokines. The CSR defect of these patients is milder than patients with AID deficiency because of residual serum IgG levels. However, their clinical phenotype is similar to AID deficiency.

Recently, nonsynonymous homozygous mutations in *INO80* have been shown to interfere with the CSR process in two siblings (Kracker et al., 2014). Mutations in *MSH6*, typically associated with colorectal cancer, have also been seen in CSR defects in a limited number of patients (Gardès et al., 2012).

Clinical manifestations

AID deficiency manifestations

Patients with AID deficiency are susceptible to severe and recurrent infections in respiratory and gastrointestinal tracts (Quartier et al., 2004). Recurrent infections lead to chronic sinusitis and bronchiectasis. Gastrointestinal infection with giardia can persist and cause malabsorption in these patients. Infections of central nervous system caused by *Haemophilus influenzae* and Herpes simplex virus (HSV) were reported in studied patients (Quartier et al., 2004). In contrast to patients with X-linked HIGM and CD40 deficiency, patients with AID deficiency are not susceptible opportunistic infection such as *Pneumocystis jirovecii* or *Cryptosporidium*. Pneumonia is in accordance with a pure B-cell deficiency. Patients are much less likely to develop neutropenia.

The hallmark of AID deficiency is enlargement of the lymphoid organs. It has been reported that 69% patients with AID deficiency develop lymphoid hyperplasia (Minegishi et al., 2000; Quartier et al., 2004; Revy et al., 2000; Zhu et al., 2003). One possible explanation for the intense lymphoid proliferation observed is the possibility that in the absence of functional AID, antigens continuously induce the proliferation of B cells, assuming that no successful antibody maturation has occurred (Fagarasan et al., 2001). It has been shown that in 75% of the cases, lymphoid hyperplasia decreases under IVIG therapy (Quartier et al., 2004).

Autoimmunity and related inflammatory disorders are the third most common complication in patients with AID deficiency, occurring in 21%, including autoimmune hepatitis, hemolytic anemia, thrombocytopenia, Crohn's disease, uveitis, chronic active hepatitis and Type 1 diabetes mellitus (Lee et al., 2005). Patients have autoantibodies of the IgM isotype (Quartier et al., 2004).

In contrast to HIGM due to defects in CD40-ligand and CD40, patients with AID mutation are generally older at age of onset, have a less severe disease and are generally recognized to have immunodeficiency later in life (Minegishi et al., 2000; Revy et al., 2000).

UNG deficiency manifestations

To date few cases of UNG deficiency have been reported in human subjects (Kavli et al., 2005). The clinical manifestations of UNG deficiency are similar to patients with AID deficiency. Patients with UNG deficiency present with a history of recurrent sinopulmonary infections and lymphoid hyperplasia and have very low serum IgG and IgA levels, increased serum IgM levels and lack of IgG antibody responses to vaccine antigens due to a profound defect of CSR. Patients have normal numbers of B- and T-cell subsets. Clinically UNG deficiency is indistinguishable from AID deficiency.

Diagnosis

The most important laboratory criterion for establishing the diagnosis of Hyper IgM is a low serum IgG, IgA, and IgE concentration and normal or elevated serum IgM levels. Antibody responses in these patients are restricted to the IgM isotype (Notarangelo et al., 2006, 2007). In contrast to patients with X-linked hyper-IgM and CD40 deficiency who have minimal lymphoid tissue, most patients with AID deficiency have prominent lymphadenopathy and tonsillar hypertrophy. Definitive diagnosis is made by mutation analysis and detection of *AID* or *UNG* mutations (Quartier et al., 2004).

Treatment and prognosis

The mainstay of treatment for HIGM is IgRT that effectively reduces the incidence and severity of infectious complications in this group of patients.

IVIG can be used on a regular basis to maintain a trough level of 400–500 mg/dl. It has been shown that IVIG also decrease lymphoid hyperplasia (Quartier et al., 2004). Every acute infectious episode should be treated with antibiotics. As a general rule, adverse reactions to immunoglobulin administration should be monitored during therapy.

Isotype, light chain, or functional deficiencies with generally normal numbers of B cells

(Ig heavy chain mutations and deletions, κ light chain deficiency, Isolated IgG subclass deficiency, IgA with IgG subclass deficiency).

Pathogenesis

Human IgG is subdivided into four subclasses, IgG1, IgG2, IgG3 and IgG4, each encoded by a separate constant (C) region gene and endowed with unique biological and functional properties. IgG1 makes up most of the total IgG (66%), followed by IgG2 (24%), IgG3 (7%) and IgG4 (3%). IgG1 and IgG3 appear early in ontogeny (Maguire et al., 2002; Schur et al., 1970), are efficient activators of the classical complement pathway (Bruggemann et al., 1987; Dangel et al., 1988) and are directed mainly against protein antigens. IgG2 contains the preponderance of antibodies to polysaccharide antigens of encapsulated bacteria. IgG2 subclass serum levels do not reach adult levels until 5–10 years of age. Other differences include a shorter half-life for IgG3, and less placental passage for IgG2.

IgG subclass deficiency was first described in Schur et al. (1970). It is defined as a deficiency of one or more IgG subclasses, (less than 2 SD below the mean for age) in the presence of normal total IgG levels (Lemmon and Knutsen, 2006; Maguire et al., 2002). In most patients, the IgM level is normal. In some patients, abnormal IgG subclasses are associated with a low level of IgA (French et al., 1995). The clinical significance of IgG subclass deficiency in patients with recurrent infections is unclear (Buckley, 2002; Maguire et al., 2002) since almost 2.3% of the general population have an IgG subclass deficiency of one or more IgG subclasses. Therefore, a low level of one or more IgG subclasses alone is generally not considered sufficient for a diagnosis of immunodeficiency.

The basic pathogenesis causing IgG subclass deficiencies is unknown. In a few cases the lack of expression of Ig isotypes has been shown to be due to homozygous deletions of the corresponding C region genes (Bottaro et al., 1990; Migone et al., 1984; Olsson et al., 1993; Pan and Hammarstrom, 2000; Smith et al., 1989). Most IgG subclass deficiencies are due to dysregulation of the expression of the γ genes.

The most common type of IgG subclass deficiency is IgG4 deficiency (40%), followed by IgG2 deficiency (28%), IgG3 deficiency (17%) and IgG1 deficiency (14%). Isolated IgG1 deficiency is rare, since a deficiency of this subclass usually result in a decreased level of total IgG.

Immunoglobulin heavy chain deletion is an autosomal recessive disease, caused by chromosomal deletion of a cluster of genes, the IgG heavy chain locus (*IGHC*, OMIM*147100), at 14q32. One or more IgG and/or IgA subclasses as well as IgE may be absent, but some affected cases may be asymptomatic (Plebani et al., 1993; Brusco et al., 1999; Geha et al., 2007).

κ light chain deficiency is an autosomal recessive disease caused by mutations in immunoglobulin kappa constant region (*IGKC*, OMIM*147200) gene, located on chromosome 2p11. Although this disease could be seen in association with some other conditions, it could also be asymptomatic. The pathogenesis of the disease is failure to express kappa chains, but the reason is unknown (Bernier et al., 1972; Liu et al., 2005; Stavnezer-Nordgren et al., 1985; Zegers et al., 1976).

Clinical manifestations

The most frequent complication observed in patients with low levels of 1 or more IgG subclasses is recurrent respiratory infections including otitis, sinusitis and bronchitis (Plebani et al., 1985; Shackelford et al., 1986; Shield et al., 1992; Umetsu et al., 1985, 1986) mainly caused by encapsulated bacteria. Serious systemic infections (e.g., sepsis, pneumonia, meningitis, cellulitis) are less common. Some patients also exhibit frequent viral illnesses. Environmental allergy is also frequently encountered in patients with IgG subclass deficiency (Lacombe et al., 1997) and many patients are atopic, and asthmatic bronchitis often accompanies the respiratory infections.

IgG2 deficiency is the most common subclass disorder associated with recurrent infection and may be accompanied by IgA and or IgG4 deficiencies. Many of these patients have impaired polysaccharide responsiveness. IgG4 deficiency, the most common form of IgG subclass deficiency, is usually not of clinical significance. However recurrent pneumonia and bronchiectasis have been described.

Diagnosis

In patients with history of recurrent respiratory infections and normal IgG levels, IgG subclass should be considered. IgG subclass levels must be compared with age-matched controls (Plebani et al., 1989). In some cases, the total IgG level may be low; in such a circumstance it should be determined whether a diagnosis of CVID might be more appropriate, especially if there is impaired specific antibody production.

Insufficient polysaccharide responses are observed commonly among young patients with IgG2 subclass deficiency (Umetsu et al., 1985, 1986). A clinically significant IgG subclass deficiency must be established by measuring the antibody response to a vaccine antigen, particularly pneumococcal polysaccharide vaccine. Impaired antibody production may not be seen among adult patients with IgG3 subclass deficiency (Barlan et al., 1993). In individuals with recurrent infections and low levels of one or more IgG subclasses, a demonstrable impairment in antibody response to vaccination is considered the most important determinant of disease (Buckley, 2002). Susceptibility to infection may wane over time, although immunologic abnormalities may persist (Herrod, 1997).

Tests for cellular immunity, complement activity and phagocytic function should be taken into consideration based on the clinical history of the patients under investigation. Chest X-ray, sinus imaging, and pulmonary function studies should be considered.

Treatment and prognosis

Asymptomatic patients with IgG subclass deficiency and normal antibody responses to polysaccharide antigens need no therapy. Many patients do well with prompt medical management and early use of antibiotics in the course of a respiratory infectious episode.

Some patients with recurrent infections or chronic respiratory infections need to be treated with prophylactic antibiotics, particularly during the winter months. Patients with severe symptoms and persistent radiographic abnormalities despite prolonged use of prophylactic antibiotics may benefit from IVIG therapy at the usual therapeutic doses. The presence of a subclass deficiency alone is not an indication for IVIG.

Some children may recover from a subclass deficiency spontaneously, particularly if there is not a complete absence of the subclass. In contrast, a subgroup of symptomatic patients can progress to common variable immunodeficiency. Therefore, a repeat immunoglobulin determination at yearly intervals is indicated in patients with IgG subclass deficiency.

Abbreviations

AD	autosomal dominant
AR	autosomal recessive
CGD	chronic granulomatous disease
CyN	cyclic neutropenia
ER	endoplasmic reticulum
G-CSF	granulocyte-colony stimulating factor
GFI1	growth factor independent-1
H ₂ O ₂	hydrogen peroxide
HAX1	HCLS1-associated protein X-1
HSCT	hematopoietic stem cell transplantation
ICAMs	intracellular adhesion molecules
LAD	leukocyte adhesion deficiency
NADPH	nicotinamide adenine dinucleotide phosphate
NBT	nitroblue tetrazolium
NE	neutrophil elastase
ROS	reactive oxygen species
SCN	severe congenital neutropenia
SLeX (CD15a)	sialyl Lewis X
WASP	Wiskott-Aldrich syndrome protein
XLN	X-linked neutropenia

Introduction

More than 100 years ago, George Bernard Shaw wrote in Act 1 of his famous play, *The Doctor's Dilemma*, "There is at bottom only one genuinely scientific treatment for all diseases, and that is to stimulate the phagocytes" (Martinez and Gordon, 2015). Indeed, neutrophils play an essential role in the innate immune response of the human body. The role of neutrophils in phagocytosis, was observed in 1884 by Metchnikov, who coined the name phagocytes for this group of blood cells (reviewed by Dale et al., 2008).

Neutrophils are the first mediators of the rapid innate host defense against various infectious agents, which occurs before the humoral and cellular adaptive immune responses are activated (Mantovani et al., 2011). Neutrophils are produced in the bone marrow from committed hematopoietic progenitor cells—common myeloid progenitors—which in turn are transformed to granulocyte-monocyte progenitors that mature into neutrophils (reviewed by Cowland and Borregaard, 2016). This process is regulated by many different transcriptional factors (Manz and Boettcher, 2014), and involves progression through the promyelocyte, myelocyte, metamyelocyte, band cell, and finally polymorphonuclear segmented cell stages (Klein, 2011). Fully differentiated neutrophils are released into the circulation in response to infectious stimuli. The regulation of both granulopoiesis and neutrophil release from the bone marrow is governed by granulocyte-colony stimulating factor (G-CSF) (Chatta et al., 1994). Millions of cells are released every day into the circulation and their life span is very short. They remain 4–6 h in the circulation and can survive up to 2 days in other body tissues (Dale et al., 2008). The four major categories of neutrophil defects affect production, blood vessel emigration, tissue migration, and bacterial killing (Fig. 1).

This review focusses only on the primary genetic disorders in each category.

Severe congenital neutropenia

Severe congenital neutropenia (SCN) is a group of inherited disorders in which there is a defect in granulocyte maturation in the bone marrow. Generally, neutropenia is defined as less than 1500 granulocyte/ μ L; but severe neutropenia, which is associated with serious infections, is observed with less than 500 cells/ μ L. Infections start early in life and usually involve the lungs, skin, and mucosal surfaces. Periodontitis and gingivitis are common features later in life (Zeidler et al., 2000). A large variety of gram-positive and gram-negative bacteria, as well as fungal infection, can cause deep-seated and severe infections (Klein, 2020). Without appropriate treatment, more than 80% of SCN patients may die from infections in early childhood (Gilman et al., 1970).

Kostmann (1950) was the first to recognize SCN as a genetic condition, describing children with an autosomal recessive trait. Subsequently, cases with autosomal dominant inheritance were discovered. Today mutations in more than 25 distinct genes have been associated with SCN (Klein, 2020; Skokowa et al., 2017). Nevertheless, in more than 20% of the cases a genetic mutation has not been found. The prevalence of SCN appears to range from 0.77 to 6 per one million, depending on ethnicity (Klein, 2020).

The diagnosis of SCN relies on clinical, hematological, and genetic findings. In most cases, infants under 1 year of age will present with a serious infection and the blood count will show severe neutropenia.

Fig. 1 Position of neutrophil defects: (1) severe congenital neutropenia; (2) leukocyte adhesion defects; (3) motility defects; (4) chronic granulomatous disease.

It should be noted that the most common cause of infant neutropenia is viral infection, in which case the neutropenia resolves spontaneously after several months (Dale, 2017). Only those cases with severe infections and persistent neutropenia should be further evaluated with bone marrow aspiration. In classic SCN, only a few normal neutrophil granulocytes are seen, indicating maturation arrest (Donadieu et al., 2017). Genetic testing is gaining an increasing role in its diagnosis. Since mutations in *ELANE* account for approximately 50% of the cases (Skokowa et al., 2017), one should begin by looking at the *ELANE* gene. If no mutation is found, a panel of genes reported to be associated with SCN can be requested. Finally, whole exome sequencing provides an opportunity to look for additional genes that may be involved in the disease.

In cases of severe infection, intravenous broad-spectrum antibiotics should be started. While in the past the only definite therapy was hematopoietic stem cell transplantation (HSCT), today every SCN case should be initially treated with G-CSF (Dale et al., 2017). Most patients respond well to 3–5 µg/Kg G-CSF, with an increase of the neutrophils to above 1500 µL and a marked decrease in episodes of sepsis (Zeidler and Welte, 2007). It seems that by increasing G-CSFR mediated signaling, G-CSF therapy induces compensatory mechanisms of granulopoiesis in SCN patients. In those few cases, where increasing the dose to 50 µg/Kg has no effect on granulopoiesis, HSCT is indicated (Rosenberg et al., 2006). Aside from failure to respond to G-CSF, another indication for HSCT is development of leukemia. The pathophysiology of leukemogenesis involves mainly somatic mutations in the *CSF3R* gene and high therapeutic doses of G-CSF (Germeshausen et al., 2007). The outcome of transplantation without malignancy is very good, with a 90% survival rate; however if leukemia is present, survival is only about 50% (Connelly et al., 2012). Recently, the use of ex vivo CRISPR/Cas9 mediated *ELANE* knockout in patient hematopoietic stem cells followed by autologous transplantation was suggested as a future alternative therapy for SCN (Nasri et al., 2020).

Specific defects in severe congenital neutropenia

Several excellent reviews have been published recently, which discuss all presently known defective genes associated with SCN (Klein, 2020; Skokowa et al., 2017); therefore this section only concentrates on the more common genetic defects.

ELANE mutations

In 1999, using a genome wide screen for genetic linkage, Horwitz et al. (1999) studied 13 families with cyclic neutropenia (CyN). All patients were found to have autosomal dominant (AD) heterozygous mutations in the *ELANE* gene, which is located at the end of the short arm of chromosome 9. A year later the same group reported that more than 50% of SCN cases harbor AD mutations in the *ELANE* gene (Dale et al., 2000). To date, more than 100 unique mutations in the *ELANE* gene have been detected which are randomly distributed across all exons (Makaryan et al., 2015). Generally, no genotype-phenotype correlation exists and the same mutation can cause SCN in one patient and CyN in another (Makaryan et al., 2015).

ELANE encodes for neutrophil elastase (NE), which belong to a class of cytotoxic serine proteases and is involved in several intracellular processes. It is expressed exclusively in mature myelomonocytic cells and their precursors (Takahashi et al., 1988). Since NE is a protease, it was reasonable to think that mutations would affect its enzymatic properties. But, in fact, protease activity is not defective since the mutant elastase has no effect on the normal NE (Horwitz et al., 2007). Several theories have been proposed to explain the granulocyte maturation arrest seen in *ELANE* mutations. The prevailing theory is as follows: since the mutant NE cannot be properly folded, it accumulates intracellularly, induces reticulum endoplasmic stress, and activates the unfolded protein response (Nanua et al., 2011). This response has evolved to protect cells from the damaging effect of improperly folded protein (Zhang and Kaufman, 2008). Therefore, the unfolded protein response initiates cell apoptosis to overcome potential damage to the integrity and maintenance of the stem cell pool. Indeed, increased apoptosis has been observed in NE mutant cells (Kollner et al., 2006; Grenda et al., 2007). While this theory can explain the pathophysiology of neutropenia, it is not clear how the same mutation can lead to SCN in one patient, while another one suffers from CyN. Recently, it was suggested that some hematopoietic stem cell progenitor cells escape the unfolded protein response and can proliferate in response to G-CSF, up to a certain threshold, at which point, the stress response again affects the majority of cells. This can lead to the cyclic balance between the proliferative effects of G-CSF on the one hand, and the stress-induced apoptosis on the other hand, eventually causing CyN (Mir et al., 2020).

HAX1 deficiency

Kostmann originally described a syndrome that was named after him, in which patients had autosomal recessive inheritance (Kostmann, 1950), and thus could not have had *ELANE* mutations. In 2007, Klein et al. (2007) described a mutation in the HCLS1-associated protein X-1 (HAX1) in DNA samples from the original Kostmann cases, as well as in other SCN patients with autosomal recessive inheritance. Thus, today Kostmann Syndrome is confined only to patients with biallelic HAX1 mutations (Klein, 2020). Although relatively rare, HAX1 mutations are more frequent in Europe (11% of SCN) than in the United States due to higher consanguinity in several European countries (Skokowa et al., 2017). HAX1 is located mainly in the mitochondria but can also be found in other parts of the cell. Its exact function remains unclear, but several studies have shown an antiapoptotic effect (Klein et al., 2007). HAX1 has also been reported to be involved in calcium homeostasis, cell motility and other cell functions. There are two HAX1 splice isoforms, A and B. Mutations affecting both isoforms lead to SCN with neurological symptoms. Mutations occurring only in isoform A cause SCN with no neurological manifestations, indicating a genotype-phenotype association

(Germeshausen et al., 2008). Since HAX1 regulates the inner mitochondrial membrane potential, it has been proposed that HAX1 mutation cause apoptosis due to mitochondrial disruption and thus may contribute to the pathogenesis of neutropenia (Klein et al., 2007). However, the exact mechanism remains elusive. Most cases of HAX1 deficiency respond very well to G-CSF therapy; however, in rare cases, especially if leukemia occurs, HSCT is considered treatment of choice. Hematopoietic stem cell gene transfer or genetic correction of induced pluripotent stem cells may in the future offer an alternative approach for a cure (Morishima et al., 2014).

Jagunal homolog 1 (*JAGN1*) deficiency

Using homozygosity mapping and exome sequencing, several cases of SCN were found to have AR mutations in the *JAGN1* gene located on chromosome 3 (Boztug et al., 2014). Clinically, these cases are very similar to patients with *ELANE* or HAX1 mutations. In some *JAGN1*-deficient patients, bone and teeth defects associated with short stature occur (Skokowa et al., 2017). No genotype-phenotype correlation was observed in patients with *JAGN1* mutations. *JAGN1* is located in the endoplasmic reticulum (ER) and plays a role in protein transport from the ER to the Golgi apparatus (Klein, 2016). The neutrophils of *JAGN1*-deficient patients have ultrastructural defects, mainly in the ER, a reduced number of granules and increased apoptosis, and defective N-glycosylation of multiple proteins (Boztug et al., 2014). Since the G-CSF receptor is also poorly glycosylated, the clinical response to G-CSF in *JAGN1* deficient patients is not as favorable compared to cases of *ELANE* or HAX1 deficiency (Klein, 2016). It is not clear why these patients suffer only from neutropenia, as *JAGN1* is ubiquitously expressed. *JAGN1* also plays a role in antifungal defense and it was recently found that myeloperoxidase (MPO), an important player in antifungal defense, is markedly reduced in patient cells (Khandagale et al., 2018). Interestingly, GM-CSF but not G-CSF, restores MPO expression in the cells of these patients, suggesting a novel therapeutic option for this condition.

Growth factor independent-1 deficiency

Since mice lacking growth factor independent-1 (GFI1) have been found to be neutropenic, a genetic analysis was performed in SCN patients without an *ELANE* or HAX1 mutation. Several cases of AD GFI1 mutations were identified (Person et al., 2003). GFI1 is a zinc finger transcriptional repressor that controls hematopoietic stem cell self-renewal and differentiation. It has been implicated in the transcriptional control of various genes important for granulopoiesis, including *ELANE* (Horman et al., 2009). GFI1 has also emerged as a critical factor in granulopoiesis due to its multiple regulatory functions. Several distinct heterozygous mutations have been identified, which generate dominant negative GFI1 variants and thus interfere with transcriptional networks, leading to maturation arrest in the myeloid lineage (Zarebski et al., 2008). Aside from severe neutropenia, affected patients have marked monocytosis. It was proposed that wild type GFI1 represses *ELANE* protein expression, thus linking mutations in the two genes to a common phenotype (Person et al., 2003).

X-linked neutropenia due to *WAS* gene mutation

While all known SCN gene mutations are classified as loss of function mutations and are transmitted as autosomal recessive or dominant traits, several patients with SCN have been found to harbor mutations in the Wiskott-Aldrich syndrome (*WAS*) gene, which is located on the X-chromosome (Devriendt et al., 2001). Most mutations in this gene cause the classical Wiskott-Aldrich syndrome or X-linked thrombocytopenia and are loss of function mutations. However, in X-linked neutropenia (XLN) the mutations lead to gain of function (GOF) resulting in a constitutively active WAS protein (WASP) expression. These GOF mutations are located in the region encoding the conserved GTPase binding domain, which allows auto-inhibition of WASP (Kim et al., 2000); therefore, mutations in this domain will lead to a continuously activated WAS protein (Devriendt et al., 2001), decreased stability of the auto-inhibited structure of WASP and thereby stimulating actin polymerization. The exact role of the GOF WAS mutations in causing maturation arrest of neutrophils is not clear. It has been suggested that the constitutive activation of WASP causing increased F-actin polymerization might account for the neutropenia (Devriendt et al., 2001). Using a mouse model, it was observed that WASP activating mutations also interfere with lymphocyte cell survival and alter cytoskeleton responses (Westerberg et al., 2010). Interestingly, the small number of neutrophils that exist in the blood are hyperactive, which may explain the milder clinical symptoms of XLN patients compared to other forms of SCN (Keszei et al., 2018).

Leukocyte adhesion deficiency (LAD)

Once the neutrophils are mature, have exited the bone marrow, and entered the blood stream, they must adhere to the vessel endothelium in order to transmigrate and enter the tissue inflammation site. This emigration is highly dynamic, involving the multi-step leukocyte adhesion cascade, which is mediated by several families of leukocyte and endothelial adhesion molecules (Etzioni and Alon, 2014). There are four distinct phases in the adhesion cascade which are critical to this cascade: rolling, integrin activation, firm adhesion, and transmigration.

Under normal conditions, leukocytes speed through the blood vessels with the normal shear flow and do not adhere to the endothelium. When inflammation occurs, the resulting chemokines and cytokines activate the endothelial cells on the blood vessels to express molecules that slow the velocity of leukocytes which begin to roll along the venular wall. This rolling phase is mainly mediated by selectins, which are expressed only after endothelial cell activation, interacting with their ligands that are constitutively present on leukocytes. The three selectins E, L, and P, bind to their ligands, which share a core of sialylated and fucosylated lactosamine tetrasaccharides, known as Lewis X (SLeX, CD15a) (Zarbock et al., 2011). Following the rolling phase, integrins mediate firm adhesion of the leukocyte to the endothelial wall. However, a prior activation process of these molecules is mandatory (Sun et al., 2019). Upon leukocyte activation by different mediators, mainly chemokines generated from the inflamed area, the integrins undergo transformational changes from a low to high affinity state (Shattil et al., 2010). The full integrin activation process leads to the next phase, referred to as “the sticking” or “the firm arrest step,” which occurs through the binding of the activated integrins to their ligands. The main ligands on the vascular endothelium are members of the immunoglobulin superfamily: the intracellular adhesion molecules (ICAMs). The final step of the extravasation process is the trans-endothelial movement of the leukocytes by diapedesis from the blood vessel to the surrounding tissue (Schmidt et al., 2013).

The importance of this orchestrated adhesion cascade was shown when specific genetic defects in the various phases of the process were discovered, leading to severe clinical symptoms. To date, defects in the first three steps of the adhesion cascade have been identified, and they all share two main manifestations: A very high leukocyte count that can exceed 100,000/mL, and a tendency for severe bacterial infections with defective wound healing (Etzioni and Alon, 2014).

LAD-1

LAD-1 was the first and the most frequent LAD syndrome to be recognized. Described originally almost 40 years ago, to date hundreds of patients worldwide have been diagnosed (Novara et al., 2018). As an autosomal recessive disease, an increase incidence has been found in countries with high consanguinity. The primary genetic defect, mutations in the gene encoding the beta subunit of integrin (CD18) (Van de Vijver et al., 2012), leads to a decrease or absence of CD18 expression on the leukocyte surface, resulting in a markedly defective firm adhesion on the vascular endothelium. While patients’ leukocytes can roll normally along the endothelium, they fail to stop and therefore cannot exit the blood vessels to reach sites of inflammation (Fischer et al., 1988). LD-1 is characterized by delayed separation of the umbilical cord, recurrent severe soft tissue infections, impaired wound healing, and marked leukocytosis (van de Vijver et al., 2013). The clinical severity and magnitude of the functional deficit of LAD-1 are directly related to the degree of CD18 expression deficiency. Patients with less than 1% expression suffer from a severe form of LAD-1 and will usually not survive beyond infancy. Those with 2–20% expression have the moderate form, and with antibiotic therapy can achieve adulthood (Hanna and Etzioni, 2012).

Initial clinical symptoms are severe omphalitis together with delayed separation of the umbilical cord. Later in life, infections—mainly of the skin and mucosal surfaces—are predominant; for those who survive infancy, severe chronic periodontitis is very common. However, it seems that the periodontitis in LAD-1 is not a pure infection; it also displays an increased potential to stimulate inflammatory responses and to particularly trigger the induction of interleukin IL-17 and IL-23-mediated immune responses in the gingival area. Indeed, ustekinumab, a human monoclonal antibody that blocks IL-23 and IL-12, has been found to be effective in reducing the oral inflammation in LAD-1 (Moutsopoulos et al., 2017). Aside from infections, a high percentage of patients with LAD-1 have also been found to suffer from autoimmune complications (De Rose et al., 2018).

In most cases, the diagnosis of LAD-1 can be established by the clinical symptoms of delayed separation of the umbilical cord, omphalitis, defective wound healing and marked leukocytosis. Flow cytometry analysis is helpful to confirm the diagnosis, and genetic testing can also be used for early prenatal diagnosis (Etzioni, 2007).

For all LAD-1 cases, prophylactic antibiotics should be started as soon as possible. In addition, for the severe form, HSCT should be performed as it has a very good survival rate (Qasim et al., 2009). While some success has been reported for gene therapy in animal models of LAD-1, it has not yet been reported in LAD-1 patients (Bauer Jr. and Hickstein, 2000).

LAD-2

LAD-2 is a very rare condition, with less than 10 cases reported worldwide. It is an autosomal recessive disorder that is characterized by marked leukocytosis, increased rate of infection, short stature, mental retardation, facial dysmorphism, and the rare Bombay blood group (Yakubenja and Wild, 2006). LAD-2 has a general defect in fucose metabolism due to mutations in *SLC35C1*, a gene that encodes the Golgi-localized GDP-fucose transporter (Lubke et al., 2001). These mutations lead to defective synthesis of various fucosylated proteins, including the selectin ligand, sialyl Lewis X (SLeX), thus causing a rolling defect in the adhesion cascade. The general defect in fucosylation also leads to the non-immunologic phenotypes of the disease, such as Bombay blood group and mental retardation (Hanna and Etzioni, 2012). In general, LAD-2 associated infections are milder than those observed in LAD-1 patients. A significant decrease in infection frequency is noticed in older children, although severe periodontitis remains their major infectious issue (Etzioni et al., 1998).

Aside from antibiotic therapy for infections, in some cases fucose supplementation can improve immunological findings (Marquardt et al., 1999). Since the mental retardation and short stature are not due to the leukocyte adhesion defect, HSCT is not recommended in LAD-2.

LAD-3

LAD-3, which has also been referred as LAD-1 variant, is a general defect in all integrins, as opposed to LAD-1 in which only the beta2-integrin is defective (Alon and Etzioni, 2003). Thus, aside from the classical LAD-1 symptoms, these patients also suffer from severe bleeding diathesis due to the activation defect in beta3-integrin (Etzioni, 2014). The condition is inherited as autosomal recessive trait, with several dozens of patients reported. All LAD-3 patients have mutations in *FERMT3*, a gene that encodes for Kindlin3 which is essential for integrin activation (Sun et al., 2019). Although integrin expression is normal on the leukocyte surface of most patients, integrin activation fails to occur after chemokine stimulation, and hence no firm adhesion of leukocyte or thrombocyte aggregation occurs (Harris et al., 2013).

Kindlin3 is exclusively expressed on hematopoietic cells and transfection of patient's lymphocytes with wild type kindlin3 restored integrin activation (Svensson et al., 2009). Due to the bleeding diathesis, patients require repeated blood transfusions. Because Kindlin3-mediated signaling by integrins is required for osteoclast-induced bone resorption, LAD-3 patients suffer from an osteopetrosis-like state (Schmidt et al., 2011). Currently, HSCT is the only curative therapy that can alleviate both the leukocyte and the platelet defects (Wolach et al., 2019).

Leukocyte migration defects

Once the leukocytes have transmigrated from the blood vessel toward the site of inflammation, they migrate toward the pathogens in a gradient dependent manner, a process known as chemotaxis. The main chemoattractant molecules that emerge from the site of a bacterial infection are fMLP and the cytokines produced by the host, mainly IL-18 (Amulic et al., 2012). The main factor ensuring leukocyte movement is the actin cytoskeleton. Actin exists in two forms: as monomers that can readily diffuse into the cytoplasm, called granular or G-actin, and as an actin filament designated F-actin, which supports the formation of the lamellipodia which are crucial for cell migration (Gressin et al., 2015). The regulation of cytoskeleton dynamics is complex and depends on a variety of actin binding proteins. Some lead to the formation of F-actin, while others are involved in severing it from G-actin. AIP1/WDR1, which is expressed in most leukocytes, enhances cofilin activity, thereby severing F-actin filaments. In order to assure an ameboid movement, the actin filaments must quickly disassemble. Several proteins were found to be involved in this process, one of which is cofilin. Actin-interacting protein 1 (Aip1), also called WD repeat containing protein 1 (WDR1), interacts with cofilin to regulate actin dynamics (Kanellos and Frame, 2016). Another important molecule is Megakaryoblastic Leukemia 1 (MKL1), which forms a complex with G-actin in the cytoplasm, and is essential for F-actin formation (Filippi, 2015).

In recent years several genetic defects caused by mutations in actin regulatory proteins were described and are referred to collectively as actinopathies.

This section focuses only on actinopathies with the main clinical symptom being a neutrophil motility defect. The reader is referred to some recent comprehensive reviews on all other disorders with a motility defect as part of the syndrome (Janssen and Geha, 2019; Burns et al., 2017).

Lazy leukocyte syndrome associated with WDR1 mutation

In 1971 Miller described two unrelated children with recurrent infections, severe stomatitis, otitis, gingivitis, and fever, but with a normal bone marrow examination. They named this new condition, "lazy leukocyte syndrome" (LLS), due to the findings of poor neutrophil chemotaxis with severely impaired random migration (Miller et al., 1971). Very few patients have been reported over the years, although it has been found that autosomal recessive mutations of actin interacting protein 1 (Aip1)—which is encoded by WDR1—were in some cases the cause of an LLS-like phenotype (Kuhns et al., 2016).

Originally it was thought that LLS was a classical immune deficiency condition of neutrophil dysfunction; however, it is now clear that in some cases autoimmunity and autoinflammation are dominant features. Although no genotype-phenotype correlation was found, a more pronounced defect has been observed only in patients with near absent WDR1 expression. WDR1, which is expressed in most leukocytes, enhances cofilin activity, which is required for severing F-actin filaments. Indeed, in LLS patients, high levels of F-actin were found, which led to defective leukocyte migration (Pfajfer et al., 2018).

LLS is not just an innate immune deficiency due to neutrophil dysfunction, but also an adaptive immune deficiency since T- and most B-cells of WDR1 deficient patients have abnormal function.

Aside from the immunological symptoms, children with LLS have facial dimorphism, severe stomatitis with oral stenosis and impaired wound healing, and in many cases intellectual disability. Without HSCT early in life, WDR1 deficient patients do not survive infancy (Pfajfer et al., 2018).

β -Actin deficiency

The β -actin gene (*ACTB*) encodes an abundant cytoskeleton housekeeping protein involved in many cellular functions, including cell motility. Only very few cases of β -actin deficiency associated with immunodeficiency have been reported. Recurrent infections, furunculosis, and septicemia were noted and associated with multisystem manifestations (Nunoi et al., 1999). The defect impairs actin polymerization resulting in abnormal neutrophil locomotion without affecting actin synthesis (Laurence, 1974). More recently it has been shown that heterozygous loss of function *ACTB* mutations cause a distinct pleiotropic malformation syndrome

with intellectual disability (Cuvertino et al., 2017). A review of 30 patients with AD ACTB mutations suggested that there could be an important mutation-specific variability in the phenotype, which does not always lead to immunodeficiency but may cause other organ defects (Sandestig et al., 2019).

Megakaryoblastic leukemia 1 deficiency

Megakaryoblastic Leukemia 1 (*MKL1*) gene, located on chromosome 22, encodes a transcription factor involved in the regulation of actin transcription as well as actin cytoskeleton-related genes. Actin polymerization releases MKL1 from the complex it forms with G-actin and allows its translocation to the nucleus where it initiates transcription of actin and actin related genes. MKL1 silencing in a myeloid cell line resulted in reduction of G-actin stores and abnormal expression of several actin-regulatory genes. Only three cases of homozygous MKL1 deficiency have been reported, all suffering from severe bacterial infections (Record et al., 2015; Sprenkeler et al., 2020). Two of the patients died of pneumonia due to progressive pseudomonas infection, while the younger patient underwent HSCT shortly after birth. A pronounced reduction in motility and chemotactic response was observed with a reduced F-actin level in neutrophils, but not in myofibroblasts (Sprenkeler et al., 2020), the latter probably due to compensatory mechanisms by MKL2 which is not expressed in neutrophils.

Despite the low number of reported patients to date, it seems that MKL1 is a non-redundant regulator of cytoskeleton associated functions involving mainly neutrophils.

ARPC1B mutation

Recently several patients with combined immune deficiency were found to have bi-allelic mutations in ARPC1B, which is part of the ARP2/3 complex. The ARP2/3 complex is involved in actin branching essential for cell migration. Loss of ARP2/3 leads to decreased lamellipodia formation, defective chemotaxis, and impaired cell migration. Mutations in ARPC1B also result in defective cytoskeletal rearrangement and altered immunological synapse formation, leading to severe loss of T-cell function (Brigida et al., 2018). Furthermore, reduced cytotoxic CD8 T-cell numbers and impaired function were observed. This is due to defects in lamellipodia formation, actin reorganization and T-cell receptor maintenance (Randzavola et al., 2019). ARPC1B-deficient platelets are micro-thrombocytes similar to those seen in Wiskott-Aldrich syndrome, are low in numbers and show aberrant spreading consistent with loss of Arp2/3 function (Kahr et al., 2017). Clinically, the disease has an early onset within the first month of life, manifesting skin rash, infections, and bleeding episodes, mainly in the gastrointestinal tract. Aside from the infections and bleeding, immune dysregulation manifestations are common and include eczema with leukocytoclastic vasculitis, arthritis, and inflammatory bowel disease (Volpi et al., 2019). Most patients require prophylactic antibiotic-treatment, and several have undergone successful HSCT, which appears to be the treatment of choice for ARPC1B deficiency.

Bacterial killing defect

After arriving at the site of infection, neutrophils must ingest and kill the pathogen. During phagocytosis of bacteria, neutrophils are activated, and a respiratory burst occurs. This oxygen consumption is essential for killing the bacteria, and is associated with the activation of the NADPH oxidase complex subunits, producing several bactericidal factors crucial for killing bacteria. The NADPH oxidase complex is comprised of five subunits. Two are membrane bound (gp91phox and p22phox) and form a heterodimer named cytochrome *b558*. Upon activation by contact with surrounding pathogens, the remaining three cytoplasmatic subunits (p47phox, p67phox and p40phox) form a heterodimer that trans-locates to cytochrome *b558* on the membrane (Anjani et al., 2020). Once activated (known as a respiratory burst), the NADPH oxidase transfers electrons to molecular oxygen and generates superoxide anion, which is dismutated to hydrogen peroxide (H₂O₂). This leads to production of other reactive oxygen species (ROS) with high microbicidal activity. Normally, the electron transfer from NADPH to molecular oxygen creates a negative charge within the phagolysosome, initiating potassium influx, which is essential for the activation of the primary granule proteins, neutrophil elastase and cathepsin G. Decrease of these two proteins is associated with defective neutrophil killing (Reeves et al., 2002).

While no defects in phagocytosis have been reported to date, a genetic defect in the killing process is not uncommon and frequently identified.

Chronic granulomatous disease

Chronic granulomatous disease (CGD) is the most common neutrophil defects, affecting 1 in 200,000 live births (Winkelstein et al., 2000). It was one of the first immunodeficiencies described and the second in which the genetic defect was found (the first being adenosine deaminase deficiency). It was initially described as “fatal granulomatous disease of childhood,” but with advances in therapeutic options and subsequently by diagnosing it in adults suffering from the disease, it is now designated as CGD. The disease can be transmitted in two forms: X-linked (~76% of cases) or autosomal recessive (AR) (24% of cases) (Winkelstein et al., 2000). The autosomal form is more prevalent in regions of the world where consanguinity is common (Wolach et al., 2017). The hallmark of CGD is the inability of the neutrophils to kill bacteria intracellularly, although phagocytosis is completely normal. Clinically, CGD is characterized not only by recurrent severe bacterial and fungal infections with tissue granuloma formation but also by an

increased incidence of inflammatory bowel disease and other autoimmune disorders including lupus, rheumatoid arthritis and Crohn's disease (Dinauer, 2019).

Mutations in all five subunits (gp91phox, p22phox, p47phox, p67phox, p40phox) of the NADPH oxidase complex were reported as causes of CGD. The *CYBB* gene, which encodes for gp91phox is located on the X-chromosome and is the most common mutation of the five subunits. The genes for the other subunits are located on different autosomes the most common being mutations in the *NCF1* gene which encodes p47phox (Roos et al., 2010). In addition to these five subunits, homozygous loss of function mutation in *CYBC1*, which is required for assembly and expression of cytochrome b558, has also been reported to cause CGD (Arnadottir et al., 2018).

Diagnosis can be made by measuring residual NADPH oxidase enzyme activity. Superoxide production can be measured by the classical Nitroblue Tetrazolium (NBT) reduction test. The generation of H₂O₂ can also be assessed using dihydrorhodamine-1,2,3 (DHR) in a flow cytometric assay (Anjani et al., 2020). Mutation analysis should be performed to identify the precise genetic defect needed for genetic counseling and prenatal diagnosis.

For many years the pathogenesis of CGD was attributed to defective ROS production, thereby impairing the killing of microorganisms, leading to severe bacterial and fungal infections. Other theories were subsequently proposed. A defective production in neutrophil elastase and cathepsin G was found to be a major factor in the pathogenesis of CGD. Indeed, these two proteins were found to be markedly decreased in cells of CGD patients, leading to a defect in intracellular killing of staphylococcus and candida (Reeves et al., 2002).

Most patients with CGD present with infections early in life, although in some cases the infections appear in adolescence or even adulthood (van den Berg et al., 2009). Patients with X-linked CGD tend to present with earlier onset and more severe disease than patients with AR-CGD (Marciano et al., 2015). CGD patients have an increased incidence of infections with catalase positive organisms such as staphylococcus, Burkholderia, and aspergillus. Common sites of infection are the lungs, lymph nodes, skin, and liver (Feld et al., 2008). Liver abscesses are usually multi-locular and need aggressive therapy (Yu et al., 2020), but surgical intervention may not be required since treatment with corticosteroids is often successful (Straughan et al., 2018). CGD patients have increased risk for infection with *Mycobacterium tuberculosis*, mainly in endemic areas, and BCG vaccination can lead to severe local and systemic disease.

Aside from severe infections, patients suffer frequently from inflammatory complications, mainly granuloma formation, colitis and increased frequency of autoimmunity. Granulomas in the gastrointestinal tract and the urinary tract can obstruct the lumen (Marciano et al., 2004). There are several theories why patients with CGD develop hyper-inflammatory conditions. It has been suggested that the lack of ROS leads to enhanced inflammation. Another mechanism points to the decreased degranulation of bacterial material causing persistent cellular activation. More recently, it was shown that CGD neutrophils produce higher amount of leukotriene B₄ (LTB₄) than normal neutrophils. LTB₄ plays an important role in lung inflammation (Song et al., 2020).

Because CGD is a chronic disorder with frequent serious complications, CGD children are reported to have more difficulties in socialization and learning, as well as emotional problems which may persist even after being treated successfully with HSCT (Pulvirenti et al., 2020).

Symptoms of infection, which can initially be quite vague, should be treated aggressively for a prolonged period of time. Microbiological diagnosis is crucial and every effort (including surgical procedures) should be made to identify the pathogen to ensure appropriate antibiotic or anti-fungal therapy.

Prophylactic antibiotics such as, trimethoprim/sulfamethoxazole, together with itraconazole have dramatically reduced the number of severe infections and are the cornerstone for successful treatment (Slack and Thomsen, 2018). The use of interferon γ is somewhat controversial: It is part of conventional prophylactic therapy in the USA, but it is not generally used in Europe (Leiding and Holland, 2020). For severe CGD cases, granulocyte transfusions have been tried, although the effect has only been anecdotally reported, without double-blind studies (Marciano et al., 2017). In view of the heterogeneity of the presentation and with many hyper-inflammatory symptoms, several new biological agents have been evaluated, but no beneficial effects have been observed so far (Dinauer, 2019).

Currently, HSCT is the only curative treatment for CGD. Excellent results have been achieved using reduced-intensity conditioning regimens, with 80–90% survival. In a recent study on 712 children and adults with CGD who underwent HSCT, the overall 3-year survival rate was 85.7%, with a low incidence of graft failure (Chiesa et al., 2020). As in many other hematopoietic genetic disorders, the possibility of gene therapy had been the subject of clinical research for two decades. While results have been poor in the past, use of the new lentiviral vector has had promising results: six out of seven patients demonstrated stable vector copy numbers and the persistence of 16–46% oxidase positive neutrophils 1 year after gene therapy. No new infections were seen and prophylactic antibiotics were discontinued (Kohn et al., 2020). Gene therapy may indeed be an excellent alternative approach for the treatment of CGD.

Introduction

Primary immune deficiency disorders (PIDD) are classically described as diseases that cause susceptibility to common and unusual infections. PIRD are monogenic causes of PIDD dominated by autoimmunity, auto- or hyper-inflammation, lymphoproliferation, malignancy, and severe atopy (Fig. 1) (Chan and Torgerson, 2020; Chan et al., 2020). The genetic variants that cause PIRD encode proteins that play essential roles in regulating immune tolerance, the inflammatory response, and malignancy eradication (Bousfiha et al., 2020). The International Union of Immunological Societies classification schema has identified over 129 PIRD within the 430 genetically described IELs (Bousfiha et al., 2020; Tangye et al., 2020).

The clinical diversity observed within PIRD stems from the genetic defects of diverse immune regulatory pathways. Multiple gene variants have been identified that contribute to PIRD pathogenesis. Tregopathies arise from defects in T regulatory cell (Treg) development or activity. Immune dysregulation, polyendocrinopathy, enteropathy, X-linked (IPEX) syndrome and related disorders are part of this category (Cepika et al., 2018). Other Tregopathies display similar clinical features and/or pathophysiology of IPEX and have thus been coined IPEX-like syndromes (Chan and Torgerson, 2020).

Non-malignant lymphoproliferation as has been described in Autoimmune Lymphoproliferative Syndrome (ALPS) encompass another subcategory of PIRD characterized by nonmalignant lymphoproliferation (López-Nevado et al., 2021). Clinical manifestations of ALPS include lymphadenopathy, splenomegaly, and autoimmunity secondary to abnormal FAS-mediated apoptosis (Oliveira et al., 2010). There are a group of diseases that present similarly to ALPS but show abnormal lymphocytic infiltration of non-lymphoid organs, which earns them the title of ALPS-like disorders. Another category of PIRD includes congenital atopic hypersensitivity with amplified atopic features. Monogenic inflammatory bowel diseases (IBD) are also included among primary immune dysregulation of the intestine that may present with other rheumatologic conditions that result from a breakdown in

Fig. 1 Symptoms of PIRD.

self-tolerance (Kelsen et al., 2020). A mixed combination of the above phenotype can also occur in PIRD when a gene defect overlaps multiple immune regulatory pathways (Chan and Torgerson, 2020).

The pathophysiology of hyperinflammation and autoimmunity in PIRD is not well understood. Overactive innate and adaptive inflammatory responses with aberrant inflammatory cytokine release including exaggerated interleukin (IL)-1 signaling, Type I Interferon (IFN) signaling, and constitutive Nuclear factor (NF)- κ B activation are commonly implicated (de Jesus et al., 2015).

The increasing understanding of PIRD pathophysiology has promoted the development of innovative precision-based therapeutic approaches by targeting specific immunological pathways. Further, the management of PIRD is often led by a multi-disciplinary team, balancing precise immune modulation and potential increased risk of infection (Chan and Torgerson, 2020). Targeted therapy has been deemed beneficial in controlling PIRD related symptoms but its role in prevention of disease manifestations is not understood. Definitive therapy with HSCT has also been effective in several PIRDs. Mechanism-based therapy in PIRD can be used as a bridge for definitive therapy with hematopoietic stem cell transplantation (HSCT) (Arnold et al., 2021).

Tregopathies

Immunodysregulation-polyendocrinopathy-enteropathy-X-linked (IPEX) syndrome

IPEX results from a germline X-linked recessive mutation in *FOXP3* which encodes a transcriptional regulator protein crucial for Tregs development (d'Hennezel et al., 2012). IPEX generally presents in early infancy with enteropathy, endocrinopathies, and other severe autoimmune phenomena (Verbsky and Chatila, 2013; Gambineri et al., 2018).

Tregs modulate the immune response by engaging with antigen presenting cells via Cytotoxic T cell Antigen (CTLA)-4, or by secretion of IL-10 and transforming growth factor (TGF)- β . The defective peripheral tolerance in IPEX leads to uncontrolled CD4+ effector T cell proliferation and lymphocytic tissue infiltration (Gambineri et al., 2018). The disorder's most prominent and common feature is enteropathy, characterized by severe watery diarrhea and malabsorption that causes failure to thrive. Under microscopy, the bowel often shows villous blunting and lymphocytic infiltration of the damaged bowel lining. Dermatologic manifestations include rashes resembling eczema and alopecia which can vary in severity. The cutaneous biopsy often shows spongiotic psoriasiform features. Type I diabetes mellitus is the most common IPEX endocrinopathy. Hematologic manifestations include autoimmune hemolytic anemia and autoimmune thrombocytopenia. Additionally, patients may present autoimmune neurological dysfunction, lymphoproliferation, and increased susceptibility to infections (d'Hennezel et al., 2012; Bennett et al., 2001; Torgerson and Ochs, 2007).

Immunophenotyping often shows diminished FOXP3+ Tregs, elevated immunoglobulin (Ig) E, and eosinophilia. Additionally, IgM and IgG can be normal to slightly low due to enteric protein loss (d'Hennezel et al., 2012). Sanger sequencing or next

generation sequencing are often used for the detection of *FOXP3* mutations (Jamee et al., 2020). Various *FOXP3* mutations have been identified in most exons, introns, upstream, and downstream (poly A) of the coding region of *FOXP3* (Bennett et al., 2000).

Affected males often die within the first or second year of life, if IPEX is left untreated (Gambineri et al., 2018). Often, treatment plans are directed at patient stabilization with total parenteral nutrition, correction of glucose abnormalities secondary to endocrine deficits, and treatment of infections prior to considering immunomodulation (Park et al., 2020). Immunosuppression is the mainstay of therapy. Corticosteroids in combination with calcineurin inhibitors such as tacrolimus and cyclosporine, are often employed in the management of IPEX (Gambineri et al., 2018; Jamee et al., 2020). Steroids alone have shown minimal effectiveness (Gambineri et al., 2018). Sirolimus has also been effectively used, particularly in patients that do not tolerate calcineurin inhibitors (Yong et al., 2008).

The use of monoclonal antibody in IPEX is often in conjunction with other immunosuppressive agents. Tumor necrosis factor (TNF)- α inhibitors, anti-CD20, and abatacept have commonly been used for treatment with mixed success. Immunomodulation in IPEX, while beneficial, has been linked to increased disease recurrence, negatively impacting long-term disease-free survival (Barzaghi et al., 2018).

HSCT remains the only definitive approach in restoring normal numbers of competent Tregs and clinical improvement even with low-level mixed donor chimerism (Barzaghi et al., 2018; Lucas et al., 2007). T cell depletion using alemtuzumab or anti-thymocyte globulin have been employed to stabilize patients prior to HSCT. In general, reduced-intensity conditioning has leads to less morbidity and mortality but increased mixed chimerism (d'Hennezel et al., 2012; Lucas et al., 2007).

Cytotoxic T-lymphocyte antigen 4 (CTLA-4) haploinsufficiency

CTLA-4 is an inhibitory regulator of T cell activation expressed by activated T cells and constitutively expressed by Tregs. CTLA-4 competes with CD28 in binding with CD80/86 on the surface of high affinity antigen presenting cells. While CTLA-4 binding provides an inhibitory response, CD28-CD80/86 binding activates T cells by co-stimulation (Farmer and Uzel, 2021). Thus, a defect in expression of CTLA-4 to increased CD28 co-stimulation, a lack of inhibition of T cell activation and ultimately the activation of self-reactive T cells against various tissues (Verma et al., 2017).

CTLA-4 haploinsufficiency presents with increased susceptibility to infections and varying forms of autoimmunity, frequently displaying incomplete penetrance and variable expressivity among members of the same family (Kuehn et al., 2014; Schwab et al., 2018). Autoimmune cytopenias, splenomegaly, and lymphocytic infiltration of non-lymphoid organs are features of CTLA-4 haploinsufficiency. Respiratory manifestations of the disease include pulmonary fibrosis, bronchiectasis, and infiltrative or granulomatous lymphocytic interstitial lung disease. Autoimmune enteropathy, autoimmune hepatitis, adrenal insufficiency, type I diabetes, arthritis, psoriasis, uveitis, and vitiligo are common CTLA-4 haploinsufficiency complications. Notably, malignancy risk for Hodgkin's lymphoma and gastric cancer is higher among this population (Verma et al., 2017; Schwab et al., 2018; Chellapandian et al., 2020).

The immunophenotype of CTLA-4 haploinsufficiency patients commonly shows hypogammaglobulinemia, decreased vaccine specific antibody titers, decreased CD19+ B cells, low switched-memory B cells, and expansion of autoreactive CD21^{low} B cells (Schwab et al., 2018; Ise et al., 2010). The T cell compartment characteristically shows increased polyclonal T cell activation, normal FOXP3+ Tregs numbers, and skewing toward a memory T cell phenotype (Verma et al., 2017; Kuehn et al., 2014).

Treatment requires attention to both the immunodeficiency and immunodysregulatory features. Immunoglobulin replacement therapy with or without prophylactic antibiotics should be considered to prevent severe infections (Verma et al., 2017). Historically, corticosteroids have been utilized to treat autoimmune enteropathy, cytopenias, infiltrative lung disease, and inflammation of the central nervous system (Schubert et al., 2014). Rapamycin has shown success in managing autoimmune cytopenias, nonmalignant lymphoproliferation affecting primarily the spleen and lymph nodes, and increased immunoglobulin consumption (Schwab et al., 2018). Other corticosteroid-sparing treatments that have been tried in the management of the multiple autoimmune complications in CTLA-4 deficiency include mycophenolate mofetil, cyclosporin, anti-thymocyte globulin, rituximab, and anti-tumor necrosis factor (TNF), all of which have shown some positive response (Verma et al., 2017). Abatacept and belatacept are CTLA-4 immunoglobulin fusion proteins (CTLA-4-Fc-IgG1) that act as soluble forms of CTLA-4. In more recent years, these mechanism-based therapies have shown promising results in a targeted approach to treating CTLA-4 functional loss (Chellapandian et al., 2020; Lee et al., 2016).

HSCT has been successful in treating severe immunodysregulatory symptoms or treatment refractory symptoms (Chellapandian et al., 2020).

Lipopolysaccharide-response beige-like anchor (LRBA) deficiency

LRBA deficiency is a autosomal recessive PIRD caused by a bi-allelic mutations in the *LRBA* (Habibi et al., 2019). LRBA is a cytoplasmatic protein that plays an essential role in regulating the traffic of intracellular vesicles, therefore preventing CTLA-4 protein lysosomal degradation, and allowing CTLA-4 re-circulation to the Tregs surface membrane (Lo et al., 2015).

The clinical spectrum of LRBA deficiency, resembles CTLA4 haploinsufficiency (Lo et al., 2015; Serwas et al., 2015). LRBA deficiency patients, most commonly present with antibody deficiency, and immunodysregulatory features such as autoimmune cytopenias, lymphocytic interstitial pneumonia, early onset type I diabetes, autoimmune hepatitis, alopecia, uveitis, and polyarthritis (Habibi et al., 2019; Kardelen et al., 2021; Lopez-Herrera et al., 2012; Alroqi et al., 2018; Gamez-Diaz et al., 2016). Malignancies such as gastric adenocarcinoma have been reported in this population (Chellapandian et al., 2020).

Neurologic disease such as central nervous system (CNS) demyelinating disease, myasthenia gravis, and brain granulomas have been reported (Gamez-Diaz et al., 2016). Immunophenotyping in LRBA deficiency, often reveals hypogammaglobulinemia, reduced switched memory B cells and plasmablasts, and variable numbers of CD4+ and/or CD8+ T cells (Habibi et al., 2019). Circulating T follicular helper (cTFH) are often increased and correlate with disease activity (Chellapandian et al., 2020).

Given the shared mechanism of disease between LRBA deficiency and CTLA-4 haploinsufficiency, both resulting in diminished CTLA-4 protein expression, abatacept has been used to treat LRBA deficiency manifestations with success as well. Abatacept has proven to be beneficial in the management of autoimmune cytopenias, interstitial lung disease, nonmalignant lymphoproliferation and autoimmune enteropathy; even though in selected cases the addition of sirolimus was necessary to achieve remission of enteropathy (Lo et al., 2015; Kiykim et al., 2019; Leiding et al., 2018). Clinical improvement with the use of abatacept correlates with reduction in cTFH, reinforcing the role of cTFH quantities as a biomarker of disease activity (Kiykim et al., 2019). HSCT has been curative for LRBA deficient patients with severe autoimmune complications (Kardelen et al., 2021; Tesch et al., 2020).

Signal transducer and activator of transcription 1 (STAT1) gain of function (GOF)

STAT1 GOF is a monogenic disorder due to heterozygous mutation in *STAT1* that confer GOF. STAT1 is a 1 of a 7-member family of transcription factors that includes essential for transmitting various cytokine signals from the cellular membrane to the nucleus to change gene expression. STAT1 in particular increased IFN- γ responsive genes.

Some of the prominent clinical features observed in STAT1 GOF include early-onset chronic mucocutaneous candidiasis, susceptibility to dimorphic fungal infections, bacterial and viral susceptibility, and immune dysregulation. Early onset type 1 diabetes, thyroid disease, autoimmune cytopenias, interstitial lung disease, and enteropathy are the most frequent immunodysregulatory features (Zhang et al., 2021a). Interestingly, patients with STAT1 GOF are also at risk of cerebral aneurysms. Cerebral aneurysms and cancers have also been noted in 6% of these patients (Toubiana et al., 2016). The pathophysiology of autoimmunity in STAT1 GOF is thought to be secondary to aberrant lymphocyte activation and signaling, abnormal Th1 and follicular helper T cell responses, impaired function of natural killer cells, and reduction in Th17 quantities (Chaimowitz et al., 2020).

Antimicrobial prophylaxis, including antifungal and antibiotics, are often first line treatment to address the increased infection susceptibility while immunoglobulin replacement therapy is often used in patients with frequent respiratory tract infections (Toubiana et al., 2016). Janus kinase (Jak) inhibitors are an emerging category of targeted therapy for patients with STAT1 GOF (Chan and Torgerson, 2020; Chellapandian et al., 2020; Chaimowitz et al., 2020; Forbes et al., 2018). HSCT for STAT1 GOF has been pursued in the setting of life-threatening complications such as severe infections, hemophagocytic lymphohistiocytosis (HLH), or refractory autoimmunity. The HSCT experience is limited ($n = 15$), with a poor overall survival (40%) and elevated rate (50%) of secondary graft failure (Leiding et al., 2018).

Signal transducer and activator of transcription 3 (STAT3) GOF

STAT3 is a transcription factor critical for various cellular processes. Heterozygous, somatic *STAT3* mutations have been described in malignancies such as large granular lymphocytic leukemia. In more recent years, germline, heterozygous GOF mutations in *STAT3* have been identified in patients presenting with early onset multi-organ autoimmunity, nonmalignant lymphoproliferation, and growth failure (Vogel et al., 2015).

On average, STAT3 GOF patients debut with symptoms at the age of 4 years (Fabre et al., 2019). Common autoimmune manifestations include autoimmune cytopenias, lymphadenopathy, splenomegaly, type I diabetes, thyroid disease, lymphocytic interstitial pneumonia, and enteropathy among others (Vogel et al., 2015). Immune phenotyping varies significantly among STAT3 GOF patients; decreased class-switched memory B cells, decreased natural killer cell numbers, reduced plasmacytoid dendritic cells, and increased double negative T cells are some of the features seen in STAT3 GOF. Additionally, some patients display low circulating FOXP3+ Tregs (Vogel et al., 2015).

Immunosuppression is the mainstay of treatment in STAT3 GOF. Tocilizumab, an IL-6 receptor blocker has been shown to be beneficial in the management of polyarthritis, scleroderma, autoimmune hepatitis, interstitial lung disease, enteropathy, and nonmalignant lymphoproliferation. Additionally Jak inhibitors such as tofacitinib, have been successful at treating life threatening disease complications (Forbes et al., 2018; Milner et al., 2015). HSCT has been performed in a very limited number of patients with one patient surviving (Leiding and Forbes, 2019).

STAT5B deficiency

STAT5b is one of two STAT5 proteins which are necessary for transducing signals to the IL-2 receptor (Verbsky and Chatila, 2011). STAT5b deficiency is an autosomal recessive disease first described in an Argentinian girl with failure to thrive, prominent forehead, saddle nose, growth failure, and delayed puberty, secondary to growth hormone deficiency (Verbsky and Chatila, 2013). Severe postnatal growth failure is primarily due to growth hormone insensitivity and severe insulin-like growth factor (IGF-1) deficiency. What distinguishes STAT5b deficiency patients from those with growth hormone insensitivity syndrome due to growth hormone receptor mutations is the presence of chronic pulmonary disease and dysregulated T cell function (Hwa et al., 2011). Other manifestations of STAT5b deficiency include growth hormone resistant failure to thrive, recurrent bacterial and viral pneumonia,

lymphoid interstitial pneumonitis, autoimmune cytopenia, eczema, and idiopathic arthritis (Verbsky and Chatila, 2013; Bezrodnik et al., 2015). Immunophenotyping often shows decreased circulating FOXP3+ Tregs, T memory phenotype skewing, presence of autoantibodies, and elevated levels of IgE (Foley et al., 2021). Patients can usually live through adulthood with supportive care; however, overall management is guided by specific end-organ pathology with antimicrobial prophylaxis and, in selected cases, solid organ transplant (e.g., lung) (Hwa et al., 2011; Kanai et al., 2012). HSCT has shown promising results in murine studies (Bezrodnik et al., 2015).

IL2R α chain or CD25 deficiency

CD25 deficiency is a rare PIRD initially described in 1997 by Sharfe et al., as a combined immunodeficiency (Roifman, 2000). CD25 deficiency results from autosomal recessive mutations in *IL2RA*. As of 2019, there were only 9 reported cases from 5 unrelated families (Vignoli et al., 2019).

CD25 (IL2R α chain) represents the alpha chain of the high affinity IL-2 receptor, a structural complex consisting of one alpha, one beta (CD122), and one gamma (CD132) subunit. This IL-2R α BY complex is constitutively expressed on Tregs and plays an essential immunoregulatory role by competing with effector T cells for IL-2 during an immune response (Verbsky and Chatila, 2011; Vignoli et al., 2019). In addition, signaling through the high affinity IL-2 receptor that includes CD25, promotes Treg transcription of *FOXP3* via the IL2/IL2R α -STAT5b transduction pathway and Treg induced IL-10 production (Zorn et al., 2006; Caudy et al., 2007). CD25 deficiency manifests similarly to IPEX with autoimmune manifestations and infection susceptibility (Vignoli et al., 2019; Caudy et al., 2007). CD25 deficiency immune-mediated features include bullous pemphigoid, autoimmune thyroiditis, and alopecia universalis (Verbsky and Chatila, 2013).

IL-15 and IL-2 use the IL-2 receptor β and γ chains for signal transduction, only differing in the alpha subunits for ligand specificity. In vitro data suggest that deficient CD25 CD4+ T cell can restore their proliferation capability when exposed to high IL-5 or IL-2, however further studies are needed in humans to assess for efficacy and safety of these agents in this study population (Caudy et al., 2007). HSCT was recently pursued in an infant with successful immune reconstitution after a second matched unrelated donor transplant with RIC (Vignoli et al., 2019).

Hyperinflammatory disorders predisposing to hemophagocytic lymphohistiocytosis (HLH)

HLH is a rare life threatening hyperinflammatory syndrome due to uncontrolled activation of cytotoxic lymphocytes and macrophages in conjunction with increased cytokine release (Chellapandian et al., 2013). Organ dysfunction in HLH (e.g., bone marrow, liver, and brain) is often mediated by activated lymphocytes and macrophages infiltration (Chan and Torgerson, 2020; Janka and Lehmborg, 2014).

The HLH 2004 diagnostic criteria constitute the most commonly used tool in both pediatric and adult populations. A patient must meet at least 5 of the 8 diagnostic criteria: fever, splenomegaly, ≥ 2 cell lineage cytopenia, hyperferritinemia, increased soluble IL2 receptor, decreased natural killer cell cytotoxicity, hemophagocytosis (in bone marrow or spleen or lymph nodes), and hypertriglyceridemia or hypofibrinogenemia (Table 1) (Lehmborg et al., 2015; Henter et al., 2007).

Primary HLH is caused by defects in genes involved in 3 immune pathways: cytolytic defects (*LYST*, *PRF1*, *RAB27A*, and *UNC13D*); signaling defects (*MAGT1* and *SH2D1A*); and inflammasome defects (*NLRP4* and *XIAP*) (Chan and Torgerson, 2020).

Table 1 Diagnostic criteria for hemophagocytic lymphohistiocytosis.

1. A molecular diagnosis consistent with HLH is made
2. Diagnostic Criteria for HLH are fulfilled (5 of 8 criteria below)
 1. Fever
 2. Splenomegaly
3. Cytopenias (affecting 2 of the 3 lineages in the peripheral blood):
 - a. Hemoglobin <90 g/L (in infants <4 weeks of age, hemoglobin <100 g/L)
 - b. Platelets $<100 \times 10^9$ /L
 - c. Neutrophils $<1.0 \times 10^9$ /L
4. Hypertriglyceridemia and/or hypofibrinogenemia
 - a. Fasting triglycerides ≥ 3.0 mmol/L (i.e., ≥ 265 mg/dL)
 - b. Fibrinogen ≤ 1.5 g/L
5. Hemophagocytosis in bone marrow or spleen or lymph nodes
6. Low or absent NK cell activity (according to local laboratory reference)
7. Ferritin ≥ 500 mg/L
8. Soluble IL-2 receptor (i.e., soluble CD25) ≥ 2400 U/mL

Adapted from Henter JL, Horne A, Aricó M et al. (2007) HLH-2004: Diagnostic and therapeutic guidelines for hemophagocytic lymphohistiocytosis. *Pediatric Blood & Cancer* 48(2):124–131.

Secondary HLH can occur secondary to severe infections, malignancies, or rheumatological conditions (e.g., systemic onset juvenile rheumatoid arthritis [sJIA]) (La Rosee et al., 2019). Once HLH criteria are met, a diagnosis can be made by assessing protein quantities encoded by HLH relevant genes. Targeted genetic testing can also aid in establishing a diagnosis. Additionally, several clinical and laboratory considerations may help distinguish some of these disorders (Canna and Marsh, 2020). For example, in a male patient with EBV-induced lymphoproliferation, X-linked lymphoproliferative syndrome(s) should be considered (Chandrakasan et al., 2019; Sepulveda and de Saint, 2017).

To effectively treat HLH, induction of remission and hyperinflammation control first must be achieved. Elimination of the eliciting trigger, and finally definitive therapy of the underlying primary disorder should follow (Arnold et al., 2021). Chemotherapeutic and potent immunosuppressive drugs such as etoposide and dexamethasone derived from HLH-94 and HLH-2004 protocols, have effectively been used to induce HLH remission (Arnold et al., 2006; Bergsten et al., 2017). A chemotherapy sparing single center ($N=38$) study of HLH patients who underwent induction of remission with steroids, anti-thymocyte globulin (ATG), and cyclosporine showed a remission rate of 70%, but increased relapse rate prior HSCT (Mahlaoui et al., 2007). Alemtuzumab (anti-CD52 humanized monoclonal antibody) co-administered with methylprednisolone and cyclosporine had a rate of remission of 64% and may constitute an acceptable alternative modality for etoposide refractory/intolerant HLH patients (Marsh et al., 2013). In a recent open label phase II-III clinical trial enrolling refractory, recurrent, progressive or intolerant to conventional HLH therapy primary HLH pediatric patients, a human anti-IFN- γ antibody: emapalumab, in combination with dexamethasone, showed significant efficacy (64.7%) in controlling HLH hyperinflammation, and an overall survival to HSCT of 79% with concomitant decrease in disease activity biomarkers such as IFN- γ and CXCL9 (Locatelli et al., 2020). Several trials are underway, assessing ruxolitinib efficacy and tolerability for treatment of secondary HLH and refractory HLH (Das et al., 2016; Albeituni et al., 2019). After remission is achieved definitive treatment with HSCT should be pursued in patients with primary HLH (Chandrakasan et al., 2019).

Autoinflammatory disorders

Autoinflammatory disorders represent a group of diseases characterized by an exaggerated and hyperinflammatory response to innate danger signals, infection, and other exogenous and endogenous factors. Inflammasomes are a key component of the innate immune system and are responsible for regulating the inflammatory response to danger signals. Through the rapid production and signaling of cytokines such as IL-1, IL-18, and IL-33, the innate immune system begins the cascade of killing and elimination of the point of danger.

TNF receptor associated periodic fever syndrome (TRAPS)

First described in 1982, TRAPS is one of the first identified autoinflammatory disorders (Menon and Efthimiou, 2018). Recessive and dominant mutations in tumor necrosis factor receptor (*TNFR1*) have been reported as has variability in penetrance. Those with high penetrance mutations present with early disease onset, whereas low penetrance mutations can manifest as an adult-onset disease with less severe features (Chan and Torgerson, 2020; Menon and Efthimiou, 2018). Patients most often present with periodic episodes of fever, pericarditis, cervical lymphadenopathy, conjunctivitis, abdominal pain, and serositis. Due to excessive chronic inflammation, a long-term complication observed in TRAPS is systemic amyloidosis with SSA fibril deposition in organs (Menon and Efthimiou, 2018).

Systemic steroids and non-steroidal anti-inflammatory drugs are often first line therapy. Targeted IL-1 inhibitor therapy with IL-1 inhibitors such as anakinra or canakinumab have been effective as well. TNF- α inhibitors are not preferred monotherapy due to high side effect profile and discontinuation rate and loss of efficacy (Menon and Efthimiou, 2018; Bettiol et al., 2019; Brogan et al., 2019).

Cryopyrin-associated periodic syndromes (CAPS) and deficiency of IL-1 receptor antagonist (DIRA)

Mutations in *NLRP3* were first described as the cause of familial cold autoinflammatory syndrome (FCAS) and Muckle-Wells Syndrome (Hoffman et al., 2001) but have now been coined as members of a larger group of disorders, cryopyrin-associated periodic syndromes (CAPS) (Martinon et al., 2002). More recently, mutations in *NLRP3* have been described as the cause of neonatal-onset multi-system inflammatory disease (NOMID) (Goldbach-Mansky et al., 2006). *NLRP3* encodes for cryopyrin, GOF autosomal dominant and de novo mutations cause *NLRP3* activation and upregulation of cleavage of inactive pro IL-1 β and pro-IL-19 into their active forms (Martinon et al., 2002). There are distinct features of FCAS, MWS, and NOMID but in general, patients present with early onset periodic fevers and arthralgias. NOMID is the most severe form of CAPS with manifestations of central nervous system involvement. DIRA is caused by biallelic loss of function mutation in *IL1RN* leading to reduced expression of an antagonist of IL-1 signaling. Patients present in the first few weeks of life with continuous fever, pustular rash, arthralgias, and periosteal lesions (Aksentijevich et al., 2009; Feldmann et al., 2002).

Three IL-1 blocking drugs are approved by the FDA for treatment of CAPS and/or DIRA (Goldbach-Mansky et al., 2006; Hoffman et al., 2004, 2008). Anakinra is a short acting recombinant IL-1 receptor antagonist that blocks IL-1 α and IL-1 β binding the IL-1 receptor; rilonacept is a fusion protein made of IL-1R1 and IL-1RAcP complexed to the Fc portion of IgG1 acting as a soluble decoy

receptor preventing interaction of IL-1 and its receptor; canakinumab is also an IL-1 fusion protein that targets IL-1 β . Canakinumab has proven to show more persistent improvement in clinical and laboratory parameters in patients with CAPS. This is likely secondary to a longer half-life (28–30 days), less frequent need for administration (every 8 weeks), and minor injection-site reactions. However, the risk of infection is higher compared to the other therapeutic choices (Brydges et al., 2013).

Familial Mediterranean fever (FMF)

FMF is the most common autosomal recessive disorder among all autoinflammatory diseases, most prevalent among people with an eastern Mediterranean or Middle eastern background. Autosomal recessive mutations in *MEFV* cause FMF (Nature Genetics, 1997). *MEFV* encodes for pyrin which is important for innate system regulated inflammasome activation. Clinical manifestations include recurrent attacks of fever, polyserositis, elevated inflammatory markers, abdominal pain, and arthralgias. Inflammatory markers are also elevated during attacks (Egeli and Ugurlu, 2020). Secondary amyloidosis and end stage renal disease are the most severe complications of FMF. For nearly 50 years, colchicine has been the mainstay of treatment. It has proven efficacy in preventing or improving inflammatory attacks and in preventing secondary amyloidosis (Zemer et al., 1974). For patients poorly responsive to colchicine, IL-1 inhibitors have been effective in reducing inflammatory attacks (Atas et al., 2021).

NLR containing CARD domain-containing protein 4 (NLRC4) gain of function

GOF mutations in *NLRC4* cause early onset autoinflammation that presents as macrophage activation syndrome or enterocolitis (Canna et al., 2014; Romberg et al., 2014). *NLRC4* activation leads to caspase-1 and caspase-8 activation and consequent overproduction of pro-inflammatory cytokines IL-18 and IL-1 β . Laboratory findings include elevated inflammatory markers and pancytopenia. Treatment with IL-1 inhibitory agents has mixed success. Recently, targeted therapy with IL-18 binding protein (tadekinig -alfa) has been successful in improving disease manifestations (Canna et al., 2017). A phase 3 clinical trial (NCT03113760) is active using IL-18 binding protein for the treatment of IL-18 driven autoinflammation including *NLRC4*.

Pyogenic, arthritis, pyoderma gangrenosum, and acne (PAPA) syndrome

PAPA is a devastating autosomal dominant disease first described in 1975 (Jacobs and Goetzl, 1975). Dominant mutations in proline-serine-threonine phosphatase-interacting protein 1 lead to hyperphosphorylation and increased binding of pyrin (Yeon et al., 2000). As a consequence, elevations in TNF- α and IL-1 β are observed (Waite et al., 2009). Clinical manifestations include early onset painful flares of recurrent sterile arthritis with a prominent neutrophilic infiltrate, skin ulceration, pyoderma gangrenosum, and cystic acne. Symptoms persist into adulthood and lead to joint destruction. IL-1 blocking agents have led to limited improvement but TNF- α inhibitors have shown promise in treating disease manifestations (Stichweh et al., 2005).

Blau syndrome

Blau Syndrome is a hyperinflammatory disease caused by mutations in nucleotide oligomerization domain protein 2 (*NOD2*). *NOD2* an intracellular bacterial pattern recognition receptor that activates receptor interacting protein2, mitogen-activated protein kinase, NFkB, to turn on antimicrobial genes. Clinical manifestations are characterized by early-onset hereditary granulomatosis with a triad of polyarthritis, rash, and uveitis (Blau, 1985). Treatment with TNF- α inhibitors have shown variable success (Nagakura et al., 2017).

Deficiency of adenosine deaminase 2 (DADA2)

DADA2 is an autosomal recessive disease secondary to LOF mutations in *ADA2* (formerly called *CECR1*) (Zhou et al., 2014). ADA proteins regulate purine metabolism by catalyzing adenosine and deoxyadenosine. ADA2 is highly expressed in monocytes and macrophages and DADA2 leads to M1 polarization of macrophages promoting inflammation and tissue damage. Clinical manifestations include: vasculopathy of small medium sized arteries, acute and chronic strokes, polyneuropathy, and vasculitis. Strokes can begin as early as infancy (Zhou et al., 2014). In a subset of patients, severe anemia may be the only symptom resembling Diamond-Blackfan anemia (Hashem et al., 2017a). Corticosteroids have been the mainstay of treatment, but TNF- α inhibitors have been shown to be effective as well (Zhang et al., 2021b). HSCT has also provided definitive therapy (Hashem et al., 2017b).

Interferonopathies

Overactivation of type I interferon response leads to type I interferon driven autoinflammatory diseases. Hyperactivation of type I interferons causes a variety of organ specific manifestations including fever with elevated inflammatory markers.

Stimulator of interferon genes (STING) -associated vasculopathy with onset in infancy (SAVI)

STING via retinoic acid-inducible gene I aids cyclic guanosine monophosphate-adenosine monophosphate synthase to recognize DNA sequences and initiate an inflammatory response. STING then signals through NFkB or interferon regulator factor 3 to stimulate the immune response (Burdette and Vance, 2013; Ishikawa and Barber, 2008). GOF mutations in *TMEM173*, which encodes for STING, cause STING associated vasculopathy (Liu et al., 2014) and familial chilblain lupus (Konig et al., 2017). Patients present with early onset rash, elevated acute phase reactants, and fever. The rash is blistering and telangiectatic and worsens with cold temperature exposure. Digital necrosis can result from the small vessel vasculopathy (Liu et al., 2014; Konig et al., 2017). Treatment with JAK-STAT inhibitors, coined jakinibs, has shown reduced disease burden (Kim et al., 2016; Sanchez et al., 2018).

Proteasome associated autoinflammatory syndromes (PRAAS)

Proteasome-autoinflammatory syndromes are caused by defects in immune proteasomes such as *PSMA3*, *PSMB8*, *PSMB9*, and *POMP* (Brehm et al., 2015; Poli et al., 2018). Mutations in proteasome subunits lead to accumulation of ubiquitinated proteins, endoplasmic reticulum stress, and an exacerbated interferon response (Manthiram et al., 2017). Clinical symptoms include chronic autoinflammation, fever, neutrophilic dermatosis, and lipodystrophy. *POMP* is a chaperone for proteasome assembly. Autosomal dominant mutations in *POMP* cause a form of PRAAS termed *POMP*-related autoinflammation and immune dysregulation (PRAID). Markedly elevated type I interferon responses occur in PRAAS. Treatment with JAK-STAT inhibitors has been effective at controlling disease related manifestations (Boyadzhiev et al., 2019). Curative treatment with HSCT has also been effective in one patient with PRAID (Martinez et al., 2021).

ALPS And ALPS-like diseases

Autoimmune lymphoproliferative syndrome (ALPS)

ALPS is a disorder of abnormal lymphocyte apoptosis associated with polyclonal populations of double negative T cells that are CD3+, express αβ antigen receptors, and are CD4- and CD8-. Multiple defects have been described among genes involved in extrinsic and intrinsic apoptosis pathways. Most patients with ALPS have variants in *FAS* or *FASL* disrupting programmed T cell death. Clinical manifestations include chronic persistent and recurrent benign lymphadenopathy, splenomegaly, hepatomegaly, and autoimmune cytopenias. Malignancies are more common in ALPS, specifically Hodgkin and non-Hodgkin lymphoma. Diagnosis relies on fulfilling a set of criteria (Table 2) (Oliveira et al., 2010; Teachey and Lambert, 2013). Immune suppression with agents such as MMF and sirolimus have proven effective (Miano et al., 2015; Rao et al., 2005).

ALPS-like diseases

Approximately 20% of ALPS patients do not have an identifiable monogenic defect. ALPS-like diseases are those primary immunodeficiency diseases that mimic an ALPS phenotype but are due to defects outside of the Fas-FasL pathway (López-Nevado et al., 2021). Patients may have similar disease manifestations but have other symptoms not consistent with ALPS, have no identified genetic variant in ALPS associated genes, and may not fulfill other diagnostic criteria for ALPS. *CTLA4* haploinsufficiency, *LRBA* deficiency, and *STAT3* GOF are classic examples of ALPS-like diseases described earlier in this chapter.

Table 2 Diagnostic criteria for autoimmune lymphoproliferative syndrome.

Required
1. Chronic non malignant lymphoproliferation (>6 months lymphadenopathy and/or splenomegaly)
2. Elevated peripheral blood αβ + CD4-CD8- T cells
Accessory
Primary
1. Defective in vitro Fas-mediated apoptosis (in 2 separate assays)
2. Somatic or germline mutation in ALPS causative gene (<i>FAS</i> , <i>FASL</i> , <i>FADD</i> , <i>CASP10</i> , <i>CASP8</i>)
Secondary
1. Elevated biomarkers (Any of following)
a. Plasma soluble FASL >200 pg/mL
b. Plasma IL-10 > 20 pg/mL
c. Plasma or serum vitamin B ₁₂ > 1500 ng/L
d. Plasma IL-18 > 500 pg/mL
2. Immunohistochemical findings consistent with ALPS as determined by experienced histopathologist
3. Autoimmune cytopenias and polyclonal hypergammaglobulinemia
4. Family history of ALPS or nonmalignant lymphoproliferation

Definitive Diagnosis: Required plus 1 primary accessory criterion.
Probable Diagnosis: Required plus 1 secondary accessory criterion.
Modified from Teachey DT and Lambert MP (2013) New advances in the diagnosis and treatment of autoimmune lymphoproliferative syndrome. *Current Opinion in Pediatrics* 24:1–8, Table 2, p. 4.

Activated PI3K delta syndrome

GOF mutations in the genes encoding p110 δ (*PIK3CD*) catalytic subunit and p85 (*PI3KR1*) regulatory subunit of phosphoinositide 3-kinase (PI3K) cause a combined immunodeficiency (Coulter and Cant, 2018; Elkaim et al., 2016; Lucas et al., 2014). PI3K is a lipid kinase that phosphorylates phosphatidylinositol-4,5 biphosphate generating phosphatidylinositol 3,4,5-triphosphate. Non-malignant lymphoproliferation that manifests as lymphadenopathy, hepatosplenomegaly, nodular mucosal lymphoid hyperplasia is hallmark of the disease. Additionally, patients are predisposed to bacterial sinopulmonary infections and invasive viral infections particularly with EBV, CMV, HSV, and VZV. The immunophenotype includes B and T cell dysfunction. Immunoglobulin levels and vaccine responses are variable, serum IgM is often elevated, and reduction in naïve T cells with increased quantities of senescent T cells are observed. Immunosuppression is the mainstay of treatment; both rituximab and sirolimus have shown clinical benefit (Maccari et al., 2018). Leniolisib, a PI3K δ inhibitor is under investigation for treatment of APDS. Early results are promising showing reduction or resolution in lymphoproliferation, normalization of circulating naïve and transitional B cell quantities, decreases in IgM, and normalization of senescent T cell quantities (Rao et al., 2017). HSCT has also been successful in the treatment of several APDS patients (Nademi et al., 2017).

Very early onset inflammatory bowel disease (VEO-IBD)

Inflammatory bowel disease that presents in children < 6 years of age is considered very-early onset. Inborn errors of immunity are detected in 15–20% of patients with VEO-IBD. The VEO-IBD is a presenting or associated symptom of the primary immunodeficiency disease. Patients with infantile onset (<2 years age), perianal disease, susceptibility to infections, and abnormal family history are more likely to be affected by a monogenic disease. More than 50 genetic variants have now been described as a cause of VEO-IBD. Whole exome sequencing and targeted sequencing panes are key components of the diagnostic approach to patients with VEO-IBD (Kelsen et al., 2020).

IL-10/IL-10R deficiency

Defects in the IL-10/IL-10 receptor signaling pathway were one of the first recognized monogenic cause of VEO-IBD. IL-10 is an anti-inflammatory cytokine that maintains homeostasis through prevention of an excessive pro-inflammatory immune response. Biallelic LOF mutations in *IL10*, *IL10RA*, *IL10RB* cause severe intestinal inflammation, particularly enterocolitis, folliculitis, and perianal disease in the infantile period (Moore et al., 2001; Shim et al., 2013). HSCT has been lifesaving as treatment in these patients (Engelhardt et al., 2013).

Severe atopic disease

Primary atopic disorders are a group of monogenic inborn errors of immunity in which atopic atopy is significant symptom of disease. Atopic clinical manifestations include atopic dermatitis, allergic rhinitis, food allergy, drug allergy, and other allergic disorders. Co-morbidities such as infection susceptibility and variable immune system abnormalities occur as well. Defects in impaired T cell signaling and cytoskeletal remodeling, cytokine signaling, T cell repertoire restriction, tolerance failure, glycosylation, skin barrier disruption, and mast cell degranulation all have allergic disease as a major feature (Milner, 2020).

Conclusions

Primary Immune Regulatory Disorders are a new and evolving group of inborn errors of immunity in which immune mediated autoimmunity, hyperinflammation, and lymphoproliferation are key features. Nearly every organ system can be affected in PIRD diseases, which can delay diagnosis. Targeted therapies have become increasingly more available as the mechanism of various PIRDs is realized. Recognition of the key clinical features of PIRD are critical to establishing a diagnosis and providing targeted therapies to treat disease related manifestations.

Introduction

The human immune system, designed to provide defense against pathogens, is comprised of innate and adaptive immunity responses. The innate immune system presents fast responses that precede the adaptive responses. It is composed of a diverse range of components that need no additional training to confront a pathogen and function by means of preformed receptors. On the contrary, adaptive immunity presents slow responses by a limited variety of cells, mainly lymphocytes, which need additional training to develop unique receptors and become capable of instigating more efficient responses.

For detecting invading pathogens, the innate immune system relies upon diverse components, key members of which are cytoplasmic and membrane-bound pattern recognition receptors (PRRs), including [Toll-like receptors \(TLRs\)](#), [C-type lectin receptors \(CLRs\)](#), [NOD-like receptors \(NLRs\)](#), and [RIG-I-like receptors \(RLRs\)](#). These receptors bind to specific proteins of various microorganisms and [pathogen-associated molecular patterns \(PAMPs\)](#). The minor variety of innate immunity receptors is compensated by targeting shared microbial components and common infection danger signals ([Wong et al., 2013](#)). Some other cellular and humoral components of innate immunity include macrophages, natural killer (NK) cells, granulocytes, dendritic cells, cytokines, chemokines, defensins, and the complement system.

Genetic defects in the innate immune system cause primary immunodeficiencies (PIDs), also known as inborn errors of immunity (IEIs), resulting in increased susceptibility to serious infections by miscellaneous pathogens, such as mycobacteria, viruses, and fungi. These pathogens cause a severe form of infection in patients with PIDs while are non-pathogenic or cause mild infection in normal people. In the last three decades, there have been considerable advances in genetic and sequencing technologies, which dramatically increased our understanding of innate immunity components and receptors. Consequently, the breakthrough in the discovery of mutations enabled us to develop our knowledge of PID phenotypes affecting the innate immune system. Some of the identified mutations cause general defects in the function of innate immunity, whereas others cause more specific defects in

particular pathways of the innate immunity. Thus, a golden opportunity has been created for the clinical field to provide tentative diagnosis and proper treatment for patients. However, as the field of innate PIDs is tremendously varied, some PIDs and their pathogenesis may have not yet been identified, indicating the inevitability of further investigations.

In this chapter four groups of defects associated with innate immunity receptors and signaling will be discussed:

1. Defects in the PRRs (namely TLR, CLR, and NLR) signaling;
2. Defects causing Mendelian susceptibility to mycobacterial diseases;
3. Defects causing WHIM (Warts, Hypogammaglobulinemia, Infections and Myelokathexis) syndrome;
4. Defects causing Epidermodysplasia verruciformis.

Defects of the pattern recognition receptors

The innate immune system takes the pivotal first steps in creating a defense barrier against invading pathogens. Its ability in restraining infections early in the disease relies strongly on the deployment of germline-encoded pattern recognition receptors (PRRs), expressed mainly on immune cells. It initiates host defense against infection through the recognition of common microbial structures, termed pathogen-associated molecular patterns (PAMPs), by PRRs. To date, five main families of PRRs categorized into two groups have been described. The first group contains membrane-bound PRRs namely Toll-like receptors (TLRs) and C-type lectin receptors (CLRs), while the second group contains intracellular cytoplasmic PRRs that are Nod-like receptors (NLRs), AIM2-like receptors (ALRs), and retinoic acid-inducible gene I (RIG-I)-like receptors (RLRs). PAMPs are common conserved structures between different pathogen classes and can be nucleic acids, cell wall components, or metabolic products. PRRs can also recognize damage-associated molecular patterns (DAMPs), which are host signals associated with cell damage or death in both intracellular and extracellular spaces. Recognition of PAMPs by intracellular or membrane PRRs induces infection signals resulting in the activation of some transduction pathways that contribute to host defense in two ways. Firstly, they give rise to the synthesis of proinflammatory factors including cytokines and chemokines, and secondly, it builds a bridge between the innate and adaptive immune system and triggers the activation of adaptive immunity.

Given the fact that PRRs play a crucial role in pathogen recognition, genetic defects and polymorphisms in the genes encoding PRRs may lead to a considerable increase in susceptibility to infections, either broad or restricted and permanent or transient (Table 1). PRR-associated PIDs usually decrease in inverse proportion to patients' age, have broadly variable severity, and are quite specific for certain families of pathogens. To date, PIDs have been described in three major families of PRRs with a substantial focus on the TLR family. Enhanced practical understanding of the pathophysiology of infections have provided novel therapeutic targets.

TLRs

The discovery of the TLR family dates back to the mid-1990s when a crucial defense mechanism in flies against fungal infections by *Drosophila* Toll proteins was detected (Lemaitre et al., 1996). This led to the introduction of similar protein receptors in the human immune system called TLRs. Consequently, being important type I transmembrane proteins of the innate immunity, the TLR family in humans was extensively studied. TLRs are expressed by a wide variety of cells, including macrophages, dendritic cells, fibroblasts, endothelial and epithelial cells, and B and T lymphocytes. They recognize both DAMPs and PAMPs, resulting in induction of early response against bacteria, viruses, fungi, and parasites as well as triggering the first steps of adaptive immunity. Human innate immunity has 10 TLRs divided into intracellular and extracellular categories. The former category consists of TLR3, TLR7, TLR8, and TLR9 and the latter includes TLR1, TLR2, TLR4, TLR5, TLR6, and TLR10. As a consequence of TLRs binding to pathogenic ligands,

Table 1 Common infectious agents in human innate immunity defects.

Innate immunity defect	Examples of possible invading pathogens
IRAK/MYD88 deficiency	<i>Streptococcus pneumoniae</i> , <i>Staphylococcus aureus</i> , <i>Pseudomonas aeruginosa</i>
TLR3 deficiency	HSV-1
TLR5 deficiency	<i>Legionella pneumophila</i>
TLR4 deficiency	Gram-negative bacteria
TLR2 deficiency	<i>Mycobacterium leprae</i> , <i>Mycobacterium tuberculosis</i>
Anhidrotic ectodermal dysplasia	<i>S. pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>S. aureus</i> , <i>Mycobacteria</i> , HSV, CMV, HPV, <i>Pneumocystis jirovecii</i> , parasites
Dectin-1/CARD9 deficiency	<i>Candida</i> , invasive aspergillosis, <i>Phialophora verrucosa</i> , <i>Corynespora cassiicola</i>
MBL deficiency	<i>Neisseria meningitidis</i> , vulvovaginal candidiasis
NLRs deficiency	<i>S. aureus</i> , <i>Salmonella</i> , mucocutaneous candidiasis, <i>Giardia intestinalis</i>
MSMD	<i>Mycobacterium bovis</i> , <i>Mycobacterium avium</i> , <i>M. tuberculosis</i> , <i>Salmonella</i> , HSV-1, CMV, HHV-8
WHIM syndrome	bacterial infections, HPV, EBV
Epidermodysplasia verruciformis	HPV

HSV-1, Herpes simplex virus-1; CMV, Cytomegalovirus; HPV, Human papillomavirus; HHV-8, Human herpes virus 8; WHIM syndrome, warts, hypogammaglobulinemia, infections, and myelokathexis syndrome; MSMD, Mendelian susceptibility to mycobacterial diseases.

some signals are sent to the cell nucleus that provoke the secretion of cytokines, type I interferon (IFN), and antimicrobial peptides. This pathway also induces a cascade of adaptive immune responses that have a prolonged protective effect in the process of combating the invading pathogen.

It has been demonstrated that each TLR has a particular microbial ligand and becomes activated by specific PAMPs. TLR4 recognizes and binds to lipopolysaccharide (LPS) component of Gram-negative bacteria, heat-shock protein 60 and 70, the fusion protein of the respiratory syncytial virus, and fungal mannan (Bulut et al., 2002; Tada et al., 2002). TLR2, in concert with TLR1 or TLR6, detects peptidoglycan, lipopeptide, di- or triacylated lipoprotein of Gram-positive bacteria and regulates anti-streptococcal and anti-staphylococcal responses (Takeuchi et al., 1999, 2002). TLR3 recognizes and binds to double-stranded RNA (dsRNA), produced from many viruses during replication while TLR7/8, and TLR9 sense single-stranded RNA and bacterial and viral unmethylated CpG DNA motifs, respectively (Alexopoulou et al., 2001; Diebold et al., 2004; Heil et al., 2004; Hemmi et al., 2000). The agonist for TLR5 is flagellin protein (Gewirtz et al., 2001). TLR10 ligand has not yet been identified. However, it has been proposed that it plays a role in inflammatory regulation during viral infections (Lee et al., 2014; Oosting et al., 2014). Polymorphisms in each TLR family affect susceptibility to pathogens containing that specific ligand. The interesting characteristic of this intricate system is that as an invading pathogen contains different PAMPs, it can be recognized by different TLRs and also several structurally unrelated ligands can be detected by described TLRs. A prime example of this is the capacity of TLR4 in recognizing different ligands (Akira et al., 2006).

Several PIDs have been identified that impair TLR signaling either directly or indirectly. These immunodeficiencies affect signal transmission from TLRs to the cell nucleus and impede cytokine secretion. As the TLR signaling pathways are key elements in defending the human body against infections, the mentioned PIDs increase susceptibility to infections. The identification of patients with monogenic immunodeficiencies, including Myeloid differentiation primary response 88 (MYD88) and interleukin(IL)-1 receptor-associated kinase 4 (IRAK-4) deficiency, UNC-93B deficiency, TLR3/2/4/5 deficiency, and hypohidrotic ectodermal dysplasia with immunodeficiency, shed light on our understanding of these infections.

IRAK-4 and MYD88 deficiency

Pathogenesis and etiology

PIDs that impair TLR signaling occur due to mutations in MYD88, IRAK-4, NF- κ B essential modulator (NEMO), inhibitor of NF- κ B kinase subunit- γ (IKBK γ), inhibitor of NF- κ B kinase subunit- β (IKBK β), and NF- κ B inhibitor- α (NFKBIA). The induction of intracellular signals to instigate the release of anti-inflammatory cytokines, including Tumor necrosis factor (TNF) α , IL-1 β , IL-6, and IL-12, depends greatly on a number of adaptor molecules. MYD88 and IRAK-4 are two examples acting downstream from TLRs, the inborn errors of which evade the proper function of the TLR signaling pathway. The reason lies in the dependency of all human TLRs, with the exception of TLR3, on MYD88 and IRAK-4 for inducing intracellular signals.

Toll/IL-1 receptor (TIR) acts as an intracellular signaling domain with an important role in both TLR signaling and IL-1 receptor (IL-1R) and IL-18R. MYD88 is a TIR-containing adaptor molecule involved in TLR signaling. It leads to the activation of nuclear factor kappa B (NF- κ B) and secretion of the aforementioned cytokines via activation of a cascade of protein kinases, among which a serine-threonine kinase named IRAK-4 is of great importance (Parvaneh et al., 2008).

As MYD88 and IRAK-4 deficiencies are autosomal recessive conditions, patients may have homozygous or asymptomatic compound heterozygous mutations in IRAK-4 or MYD88. Of note is that mutations leading to IRAK-4 deficiency truncate the kinase domain and are predominantly Q293X mutations (Ku et al., 2005b).

Clinical perspective

As the function of a great number of TLRs and signaling pathways depend on IRAK-4 and MYD88, their mutations seem to cause a broad and considerable immunologic loss. However, the spectrum of infecting pathogens to which patients are vulnerable is surprisingly narrow.

MYD88 and IRAK-4 deficiency predispose patients to recurrent invasive (e.g., septicemia, meningitis, arthritis, osteomyelitis, abscesses) and non-invasive (e.g., skin and upper respiratory tract infections) pyogenic bacterial infections. Pathogens predominantly include *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa*. However, infection with other species, including salmonella, shigella sonnei, neisseria meningitides, were also reported, though not common in these patients (Medvedev et al., 2003; Chapel et al., 2005).

Despite being unable to show considerable fever and rise of systemic inflammatory markers, including C-reactive protein (CRP) plasma level, pus formation can be observed in these patients (Picard et al., 2010). Positive blood or cerebrospinal culture may be beneficial for the diagnosis. In IRAK-4 and MYD88 deficient patients, the amount of IL-6 and IL-8 released in response to IL-1 and TLR activation is small (Picard et al., 2011). The antibody response to polysaccharides can be impaired (Ku et al., 2007b; Von Bernuth et al., 2008). Separation of the umbilical cord is also delayed in these patients (Picard et al., 2010). No sign of developmental abnormalities, including ectodermal dysplasia, osteoporosis, and lymphoedema in their growth process has been observed (Bustamante et al., 2008).

The intriguing point is that although IRAK-4 and MYD88 immunodeficiency are life-threatening in the first years of life, their clinical features tend to improve with age. It has been proposed that the reason for the decrease in their frequency and severity is the efficient adaptive immune response that comes into effect to compensate for the mentioned defensive defects against infections (Puel et al., 2004). It has been demonstrated that IRAK-4-deficient patients suffer from an impaired pneumococcal-specific immunoglobulin (Ig)G response that does not always match with the occurrence of invasive bacterial infections (Picard et al.,

2010; Ku et al., 2007a; Borgers et al., 2010). Also, it has been indicated that these patients have reduced circulating IgM⁺IgD⁺CD27⁺ B cells that produce rapid T-independent IgM against bacteria, leading to increased susceptibility to infections (Weller et al., 2012). It is presumed that T-independent IgG responses mature as age increases so that they compensate impaired T-independent IgM responses and infection susceptibility diminishes in adolescence (Douglas et al., 1983).

IRAK-4-deficient patients have a narrow susceptibility to pyogenic bacterial infections, while they seem to have normal resistance against many other pathogens, including common viruses, fungi, parasites, and mycobacteria (Ku et al., 2005b) which suggests that these invading pathogens are suppressed by other signaling pathways. As an example, viral pathogens are controlled through TLR3-dependent immunity. This narrow spectrum of susceptibility also indicates the non-redundancy of the TLR system in combating pathogens (Turvey and Hawn, 2006).

Being life-threatening conditions and causing death in half of the identified patients (Picard and Casanova, 2005), IRAK-4 and MYD88 deficiencies require appropriate administration of prophylactic and therapeutic measures. It is imperative that patients receive conjugated and nonconjugated vaccines to be immunized against encapsulated bacteria, including *S. pneumoniae*, *Klebsiella*, *Haemophilus influenza*, *Neisseria meningitidis*. Moreover, prophylactic antibiotic therapy with cotrimoxazole and penicillin V throughout life is necessary for these patients (Ku et al., 2005b). Intravenous and subcutaneous immunoglobulin replacement therapy until at least the age of 10 may be of use in some patients to resist severe bacterial infections, especially those with impaired antibody response to polysaccharides (Parvaneh et al., 2008; Picard et al., 2010). Despite receiving relevant prophylaxis, it is of the utmost importance to instantly start empirical parenteral antibiotic therapy when a bacterial infection is suspected and further implement specific antibiotic treatment to prevent invasive infection and death (Picard et al., 2011).

TLR3 deficiency

Pathogenesis and etiology

A number of PIDs affecting TLR3 signaling, an MYD88-independent pathway, have been identified. They include genetic mutations of TLR3, UNC93B, Toll/IL-1R domain-containing adaptor inducing interferon- β (TRIF), TNF receptor-associated factor3 (TRAF3), and TANK-binding kinase 1 (TBK1). Viral nucleic acids can be detected by intracellular TLRs and the RIG-I helicase family. TLR3 plays an important role in our defense against viruses by recognizing double-stranded RNA.

UNC-93B was first known for its function as a regulatory subunit of a potassium channel in *Caenorhabditis elegans* (Greenwald and Horvitz, 1980). It carries out a task in human TLR signaling, including TLR3 signaling pathway (Casrouge et al., 2006; Tabeta et al., 2006) that can strongly induce IFN- α/β and - γ secretion.

Autosomal recessive UNC-93B deficiency impairs fibroblastic cell responses to TLR3 agonists of viruses. TLR3 Heterozygous mutations have been documented as a contributing factor to Herpes simplex encephalitis (HSE) in children (Zhang et al., 2007). Also, homozygous mutations of UNC-93B were found as a potent factor that makes patients highly susceptible to isolated herpes simplexvirus-1 (HSV-1) encephalitis (Casrouge et al., 2006). In this respect, studies on pluripotent stem cell-derived neurons and oligodendrocytes derived from TLR3 or UNC93B deficient patients have discovered the decreased capacity of type I IFN production and heightened vulnerability to this infection through increased viral replication and cell death (Lafaille et al., 2012). Exposure of cells to recombinant IFN β was shown to be effective in ameliorating the destructive effects of the virus (Zhang et al., 2007). Based on this evidence, we can assume that TLR3/TRIF/UNC-93B-dependent signaling pathway and interferon type I responses are crucial for defense against HSV-1.

Clinical perspective

As explained above, mutations of TLR3/UNC-93B/TRIF/TRAF3, all central in the protective mechanism against viruses, heighten the susceptibility to HSV-1 encephalitis. It is also possible to observe incomplete clinical penetrance, which means having a mutated gene while being asymptomatic (Sancho-Shimizu et al., 2011). We should note the intriguing point that the spectrum of infections observed in these children is remarkably restricted as they are affected exclusively by HSV-1 and exhibit normal resistance to other pathogens. This surprising fact implies the redundancy of the TLR3-dependent signaling pathway in human beings except for protection against HSV-1 in the central nervous system (CNS).

Infection primarily happens in early childhood though there is a possibility of its recurrence even later in life (Bousfiha et al., 2010). Clinicians should be aware that recurrent HSE infection could be a sign of TLR3/UNC-93B deficiencies; even so, conventional immunological workup shows normal results. On the contrary, L-selectin measurement following the addition of diverse TLR agonists is practical in diagnosing TLR signaling defects (Parvaneh et al., 2008). Treatment with IFN α combined with acyclovir is the proposed therapeutic strategy for managing these patients (Casrouge et al., 2006; Zhang et al., 2007).

TLR5 deficiency

Pathogenesis and etiology

Genetic polymorphism of TLR5 that recognizes flagellin of flagellated bacteria is reported to be associated with total loss of receptors and increased susceptibility to Legionnaire's disease caused by *Legionella pneumophila*. An example of these polymorphisms happens in the TLR5 ligand-binding domain (Hawn et al., 2003). However, as TLR5 polymorphisms have a considerable frequency in human population and have subtle immunodeficiency presentations, this defect is more considered as a disease risk factor rather than a classical PID, suggesting its dispensable role in host defense (Wlasiuk et al., 2009).

Clinical perspective

Individuals with TLR5 polymorphism are highly prone to infections with *L. pneumophila* and recurrent cystitis, while it is unlikely for them to become at risk of typhoid fever infection by *Salmonella Typhi* (Hawn et al., 2003, 2009; Dunstan et al., 2005). They do not present severe manifestations of the disease. Moreover, TLR5 polymorphism has been shown to exert protective effects against systemic lupus erythematosus and Crohn's disease, which is highly prevalent in carriers of NOD2 mutations (Gewirtz et al., 2006).

TLR4 deficiency

Pathogenesis and etiology

TLR4 contributes to innate immunity function by binding to its ligands, LPS and endotoxin. The most important identified TLR4-related genetic defects are Asp299Gly and Thr399Ile single nucleotide polymorphisms (SNPs), leading to an altered amino acid sequence of the extracellular domain and impaired recognition of inhaled LPS (Arbour et al., 2000).

Clinical perspective

Asp299Gly and Thr399Ile SNPs affect patients' susceptibility to Gram-negative bacteria. These conditions may also be associated with sepsis (Turvey and Hawn, 2006). The intriguing point is that these patients have shown resistance against Legionnaire's disease. This can be explained by the unusual LPS structure of this flagellated Gram-negative bacterium which is recognized by TLR2 rather than TLR4 (De Tiege et al., 2008). Also, Asp299Gly SNP was demonstrated to have no impact on susceptibility to meningococcal disease (De Tiege et al., 2008).

TLR2 deficiency

Pathogenesis and etiology

TLR2 detects Gram-positive microorganisms and mycobacteria by recognizing their lipopeptides. TLR2 SNPs, Arg753Gln and Arg677Trp, lead to defective TLR2 signaling pathways and make patients more susceptible to some infections.

Clinical perspective

Arg753Gln was demonstrated to increase patients' susceptibility to tuberculosis. However, it is interesting that this SNP evades the development of late-stage Lyme disease (Hayashi et al., 2001; Hawn et al., 2003). Arg677Trp SNP increases susceptibility toward lepromatous leprosy and tuberculosis (Hawn et al., 2005; Gewirtz et al., 2006).

TLR defects with ectodermal dysplasia

Pathogenesis and etiology

Nuclear factor kappa-light-chain-enhancer of activated B cells (NF- κ B) is a protein complex of the Rel family and a transcription factor with crucial roles in TLR-dependent inflammatory responses, cell adhesion, and cell survival (Temmerman et al., 2012). Under normal conditions, a family of inhibitors called I κ Bs (I κ B α , I κ B β , and I κ B ϵ) retain NF- κ B inactive and in the cytoplasm. Following cell stimulation via several pathways such as TLRs, IL-1R, and TNF-R, I κ B kinase (IKK) complex phosphorylate I κ Bs and lets NF- κ B move into the nucleus. IKK complex is composed of IKK α and IKK β catalytic subunits and IKK γ regulatory subunit, which is also called NF- κ B essential modulator (NEMO). NF- κ B translocation to the nucleus promotes transcription of genes that shape the host immunity system (Israel, 2000; Karin and Ben-Neriah, 2000). NEMO and I κ B α mutations bring about a rare primary immunodeficiency condition named Anhidrotic ectodermal dysplasia with immune deficiency (EDA-ID) characterized by a broad phenotype of defects in immunity, ectodermal structures and bones. EDA is not observed in other signaling defects and was the first TLR-signaling defect observed in human patients.

X-linked anhidrotic ectodermal dysplasia with immunodeficiency (XL-EDA-ID) happens due to hypomorphic mutations in the NEMO gene. It is a rare condition with a predominant incidence in male subjects; however, it can rarely happen in females as well. The first cases of XL-EDA-ID were discovered in 2000 and 2001 (Döffinger et al., 2001; Zonana et al., 2000). On the other hand, in 2003, autosomal dominant ectodermal dysplasia with immunodeficiency (AD-EDA-ID) that happens due to hypermorphic heterozygous mutation of I κ B α was discovered. This defect impedes I κ B α phosphorylation and causes NF- κ B retention in the cytoplasm, and impairs NF- κ B activation (Courtois et al., 2003).

Clinical perspective

Clinical manifestations of EDA-ID are broad and can be discussed in three subcategories:

Developmental standpoint: The wide range of developmental manifestations in EDA-ID patients mainly involve ectodermal-derived structures. Symptoms include sparse hair, thin skin, abnormal nails, Hypohidrosis, hypodontia or anodontia, heat intolerance, and in more severe cases, osteoporosis and lymphedema. However, it is possible to identify patients without EDA phenotype or with just a few signs of EDA like conical incisors and hypodontia (Ku et al., 2005a). It is also likely that patients only display the infectious signs without presenting EDA phenotype (Niehues et al., 2004; Orange et al., 2004b).

Infectious standpoint: EDA-ID patients are vulnerable to infections that affect both peripheral tissues and deep-seated tissues throughout the blood stream. The former include skin, respiratory tract, digestive tract, and their draining lymph nodes, while the latter include spleen, liver, bones, and joints. These patients present with meningitis and septicemia during infancy and may show recurrent infections with different groups of pathogens as discussed below.

The first group of pathogens that affects these subjects encompasses encapsulated invasive pyogenic bacteria, including *S. pneumoniae*, *Haemophilus influenzae*, and *S. aureus*. They lead to meningitis, sepsis, arthritis, osteomyelitis, abscesses, recurrent pneumonia with bronchiectasis, gut infection, and ENT infections.

Another group comprises mycobacteria that does not typically cause serious infection in normal individuals. Examples are *Mycobacterium kansasii*, *Mycobacterium avium*, and *Mycobacterium bovis*, causing cellulitis, osteomyelitis, lymphadenitis, pneumonia, and disseminated infections in patients (Döffinger et al., 2001; Hanson et al., 2008). In spite of the fact that these mycobacteria are weakly pathogenic, ADA-ID patients are highly susceptible to them.

Other less common pathogens include parasites, viruses, and fungi. Typical viruses that infect patients encompass herpes simplex virus (HSV), cytomegalovirus (CMV), adenovirus, Molluscum contagiosum, and human papillomavirus (HPV). They can cause herpes simplex virus encephalitis, severe adenoviral gastroenteritis, or severe cytomegalovirus infection (Döffinger et al., 2001; Uzel, 2005). *Pneumocystis jirovecii* pneumonitis is an example of opportunistic fungal infection (Orange et al., 2004a). Patients are highly susceptible to other opportunistic infections, including pulmonary pneumocystosis and chronic mucocutaneous candidiasis.

Autoimmune standpoint: Autoimmune manifestations in patients involve inflammatory bowel disease (IBD)-like colitis, hemolytic anemia, and arthritis (Niehues et al., 2004; Ørstavik et al., 2006; Uzel, 2005).

NEMO- and $\text{I}\kappa\text{B}\alpha$ -deficient patients usually have a delayed inflammatory response to severe infections. Also, many patients display a persistent abnormal antibody response to polysaccharides, giving rise to invasive pneumococcal diseases (Döffinger et al., 2001; Orange et al., 2004a; Picard et al., 2003). Nevertheless, a few patients have shown acceptable antibody responses to carbohydrates of conjugated vaccines (Ku et al., 2005). IgG hypogammaglobulinemia has been observed in a large number of patients (Courtois and Smahi, 2006). Moreover, some patients may present with hyper-IgM syndrome due to impaired CD40 signaling, which further contributes to *Pneumocystis* pneumonitis (Kenwrick et al., 2001; Seyama et al., 1999; Agou et al., 2004). In some patients, NK cell abnormalities accounting for higher susceptibility to herpes viruses have been detected (Hoffmann et al., 2003). NEMO-deficient patients may also demonstrate a lack of $\text{TNF}\alpha$ -mediated IL-10 production in whole-blood assays (Hanson et al., 2008; Puel et al., 2004). Impaired T-cell proliferation and function may be observed in some but not all patients.

A wide variety has been observed in the prognosis of these patients ranging from death in childhood to staying relatively well until older age after the application of proper prophylactic and therapeutic measures.

These patients should be immunized and vaccinated against encapsulated bacteria, including *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*. However, Bacille-Calmette-Guérin (BCG) vaccination is contraindicated for them. Intravenous and subcutaneous immunoglobulin replacement therapy is applicable for patients presenting with impaired function of B-cell immunity. Prophylactic antibiotic therapy with cotrimoxazole and penicillin V in the absence of allergy may be of use, though it is controversial. For treatment of mycobacterial infection in NEMO- and $\text{I}\kappa\text{B}\alpha$ -deficient patients, intensive four-drug regimens should be applied for at least 12 months (Parvaneh et al., 2008). It has been suggested to implement empirical parenteral antibiotic treatment against *S. pneumoniae*, *S. aureus*, *P. aeruginosa*, and *H. influenzae* prior to specific antibiotic adaptation in case of suspected infection. As these patients are susceptible to life-threatening infections, hematopoietic stem cell transplantation (HSCT) may be considered to ameliorate the immunodeficiency state (Dupuis-Girod et al., 2002; Orange et al., 2004a).

CLRs

C-type lectin receptors (CLRs), a large family of PRRs and expressed by a number of innate immune cells, especially myeloid cells, are central in signaling pathways that induce essential cytokines for T cell polarization. They can also activate NF- κB directly or indirectly via TLRs. CLRs initiate antifungal immune responses by detecting fungal carbohydrates and are capable of further regulating adaptive immune responses.

Dectin-1 and CARD9 deficiency

Pathogenesis and etiology

Dectin-1 is a CLR found on monocytes and macrophages that recognizes *Mycobacterium tuberculosis* and fungal cell wall through binding to β -1,3-glucan polymer present in the fungal cell wall. Dectin-1 bound with its ligand transmits signals to CARD9, a key regulator of inflammatory responses and consequently, antifungal immunological responses become activated.

Several individuals have been identified with dectin-1 and recessive CARD9 mutations that impair immunological pathways involving IL-17. Impairment of Th-17 dependent IL-17 production has been reported in these patients (Glocker et al., 2009). A mutation in the dectin-1-encoding gene has been identified that generates a misfolded dectin-1 molecule which is not expressed on the cell membrane. Thus, impairments in the ability of mononuclear phagocytes to bind to their ligand have been observed, which lead to mucocutaneous fungal infections (Netea et al., 2012). It is notable that these mutations are not associated with a severe PID phenotype and cause milder symptoms than classical chronic mucocutaneous candidiasis (Puel et al., 2010; Lilic et al., 2003).

The absence of severe invasive candidiasis in these patients can be explained by an observation in mononuclear phagocytes and neutrophils. It demonstrates that monocytes and macrophages of homozygous patients show an impaired cytokine release which ultimately leads to mucocutaneous fungal infections. Conversely, neutrophils display normal phagocytosis function and provide protection. This fact suggests that dectin-1 is inessential for the function of neutrophils (Ferwerda et al., 2009).

CARD9 mutations bring about more severe phenotypes compared to dectin-1 deficiency. This can be traced back to CARD9 downstream location as an adaptor molecule that receives signals from several CLRs, only one of which is dectin-1. Thus, its deficiency causes more invasive fungal infections (Savides and Shaker, 2010).

Clinical perspective

Life-threatening fungal infections are the key clinical presentation of dectin-1 and CARD9 deficiency. Leading to defective β -glucan recognition and decreased cytokine release by monocytes and macrophages, dectin-1 Y238X polymorphism increases the odds of being infected with *Candida* and invasive aspergillosis (Plantinga et al., 2009; Cunha et al., 2010; Chai et al., 2011; Sainz et al., 2012). Also, CARD9 mutation makes patients susceptible to persistent and invasive fungal infections. These predominantly involve skin, nails, scalp, mucosal tissues, occasional contiguous dissemination to subcutaneous tissue, lymph nodes, bones, and also systemic fungal diseases, a common presentation of which is meningoencephalitis and CNS involvement (Lanternier et al., 2013; Wang et al., 2014; Drummond et al., 2015; Gavino et al., 2014). Mucocutaneous candidiasis (CMC) is a term referring to Persistent and recurrent mucosal infections, which usually happen earlier than serious presentations affecting the brain (Drummond et al., 2015; Grumach et al., 2015; Lanternier et al., 2015). Pathogens include *Trichophyton* species, *Phialophora verrucosa*, and the plant pathogen *Corynespora cassiicola* (Lanternier et al., 2013; Wang et al., 2014; Yan et al., 2016).

Since acquired predisposing factors for invasive fungal infections are certain and include HSCT, immunosuppressive therapies, chemotherapy, human immunodeficiency virus (HIV) infection, Supportive Oligonucleotide Technique (SOT), and hematological malignancies, gene sequencing should be done to screen CARD9 mutations in individuals with unexplained invasive fungal disease (Limper et al., 2017; Pappas et al., 2010).

Understanding how the impairment of the CARD9 signaling pathway leads to reduced cytokine release and increased likelihood of fungal infections has enabled us to explore the field of therapeutics extensively and implement tailored treatment for the patients. Suggested treatments for fungal infections encompass life-long treatment with systemic and topical azole agents for CMC, oral azole therapy for subcutaneous infection, intravenous treatment followed by oral fluconazole consolidation therapy for Invasive *Candida* infections, topical agents for Superficial dermatophytosis, and systemic antifungal agents for Extensive/deep dermatophytosis, Onychomycosis and scalp lesions (Firinu et al., 2011; Pappas et al., 2016; Pires et al., 2014; Gupta and Cooper, 2008). In case of severe deep dermatophytosis surgery is indicated for controlling the disease progression (Pires et al., 2014; Gupta and Cooper, 2008). Local excision for extensive skin lesions, and complete removal of brain abscesses by surgery are also suggested (Oberlin et al., 2017). Immune-based Adjuvant therapies for fungal meningoencephalitis were reported effective in inducing a lasting clinical remission (Celmeli et al., 2016). Vaccination against mycobacterium tuberculosis is of use in boosting immunity in these patients (Ostrop et al., 2015).

However, reoccurrence of fungal disease after stopping treatment in CARD9 deficient patients is considerably reported. This fact elucidates the need for longer courses of treatment or life-long treatment (Corvilain et al., 2018). Allogeneic stem cell transplantation leading to leukocyte-mediated CARD9 immunity reconstitution was reported successful in inducing complete clinical remission (Queiroz-Telles et al., 2019). Moreover, granulocyte-macrophage colony-stimulating factor (GM-CSF) that recruits neutrophils and curbs CNS candidiasis brought about favorable results in CARD9-deficient patients (Gavino et al., 2014).

MBL deficiency

Pathogenesis and etiology

Mannose-binding lectin (MBL) is a soluble CLR, the deficiency of which stems from changes in the MBL2 gene. As MBL has a specific role in recognizing microorganisms, decreased MBL level predispose patients to an increased susceptibility to infections. However, MBL polymorphism is quite common in the general population and thus, accounts for an infection risk factor rather than a critical PID (Sprong and van Deuren, 2008).

Clinical perspective

MBL-deficient individuals are more susceptible to fungal, viral, and bacterial infections, including *Neisseria meningitidis*. They are also likely to present with recurrent vulvovaginal candidiasis, though it is not common in the general population (Liu et al., 2006; Donders et al., 2008; Giraldo et al., 2007; Babula et al., 2003). Therapeutic strategies for patients with relapsing infections primarily include antibiotic therapy and vaccination.

NLRs

NOD-like receptors (NLRs) are a group of intracellular PRRs. NOD1 and NOD2 constitute a group of NLRs whose function is recognizing bacterial peptidoglycans leading to nuclear translocation of NF- κ B and expression of inflammatory cytokines. NLRPs are another subgroup of NLRs that are involved in the formation of the inflammasome and activation of caspase-1 protease. This activation leads to proteolytic processing of the proinflammatory cytokines, including IL-1 β and IL-18. To date, genetic mutations and polymorphisms in several members of the NLRP family and NOD2 receptor have been described. Defective NLRPs usually cause autoinflammatory diseases stemming from the dysregulated release of IL-1 cytokines.

NOD2 deficiency**Pathogenesis and etiology**

Defects of the NOD2 gene, including a mutation in the Leucine-rich repeat (LRR) domain, have been reported in association with Crohn's disease and Blau syndrome (Hugot et al., 2001; Ogura et al., 2001; Miceli-Richard et al., 2001).

Clinical perspective

A loss-of-function genetic mutation has been reported to cause a PID of gut mucosal immunity in NOD2-deficient patients. It leads to impaired cytokine response, neutrophil function, and consequently weakened immune response against invading pathogens presenting with a granulomatous reaction. Thus, in these patients, Crohn's disease, an inflammatory bowel disease (IBD), happens due to impaired mucosal host defense (Kobayashi et al., 2005; Kullberg et al., 2008). Patients also display reduced protection against bacterial infection. On the other hand, a gain of function mutation in the NOD2 encoding gene accompanied by increased activity of transcription factor NF- κ B causes Blau syndrome. Patients display an uncontrolled granulomatous inflammation (Miceli-Richard et al., 2001).

Vitamin D treatment for upregulating NOD2 may be beneficial in enhancing immunity against invading bacteria, including *S. aureus* and *Salmonella typhimurium* (Subramanian et al., 2017; Liu et al., 2017).

NLRP3 deficiency**Pathogenesis and etiology**

NLRP3, expressed in polymorphic mononuclear cells and monocytes, is an inflammasome required for the activation of cytokine-releasing pathways. Specific gain of function mutations in the NLRP3 genes lead to a cryopyrin-associated periodic syndrome (CAPS), with the sub-syndromes of familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and chronic infantile neurological cutaneous and articular syndrome (CINCA/NOMID) (Hull et al., 2003; Aksentijevich et al., 2002; Hoffman et al., 2001; Aganna et al., 2002). The range of symptoms varies from mild to severe, and patients may present with overlapping symptoms of the three aforementioned phenomena (Van Der Made et al., 2020).

Clinical perspective

All these phenotypes cause systemic inflammation with fever, raised CRP level, and neutropenia. Also, localized neutrophilic inflammation in skin, joints, muscles, conjunctiva, and cerebrospinal fluid has been detected. FCAS phenotype is associated with fever, systemic symptoms, non-pruritic urticaria-like rash, conjunctivitis, and arthralgia, all of which happen after exposure to cold (Hoffman et al., 2001). In MWS-affected patients, the same symptoms can be observed, though without specific relation to cold. Sensorineural hearing loss and amyloidosis have a higher incidence in these patients. Conversely, conjunctivitis is less probable in them (Aganna et al., 2002). Manifestations of NOMID patients include fever, urticaria, deforming arthropathy, epiphyseal overgrowth of the long bones, and chronic meningitis, uveitis, and sensorineural hearing loss (Aksentijevich et al., 2002).

Therapeutic strategies include rilonacept and interleukin-1 trap, canakinumab, an antibody that neutralizes IL-1 β , and anakinra, an antagonist of IL-1 α receptor, all of which have shown favorable results (De Koning et al., 2015; Jesus and Goldbach-Mansky, 2014).

NLRP12 deficiency**Pathogenesis and etiology**

NLRP12 is another inflammasome whose gain of function mutations also cause FCAS, though with milder presentations. Autoinflammatory disorders, Crohn's disease, and heightened susceptibility to infections are consequences of NLRP12 mutations (Kostik et al., 2018).

Clinical perspective

Patients have been reported with negatively regulated TNF- α induced NF- κ B signaling (Allen et al., 2012). They were treated with anakinra. However, recurrence happened with an increased TNF- α level (Jeru et al., 2011). Glucocorticoids, non-steroidal anti-inflammatory drugs (NSAIDs), IL-1 blockade therapy, and anti-TNF- α therapy for Crohn's disease are other therapeutic choices that result in better clinical response (Başaran et al., 2018; Kostik et al., 2018).

NLRP1 deficiency**Pathogenesis and etiology**

NLRP1 mutations cause a wide range of symptoms. The reason lies in the fact that NLRP1 is expressed by a large number of cells, including myeloid cells, T-cells, and Langerhans cells. Thus, the dysregulated function of NLRP1-induced pathways causes multiple symptoms, including various autoimmune disorders. Mutations can be found between the NACHT and LRR domains and in the function-to-find (FIIND) domain (Grandemange et al., 2017).

Clinical perspective

Autoimmune phenotypes comprise autoimmune hemolytic anemia, diabetes type I, Addison's disease, autoimmune thyroiditis, celiac disease, Systemic lupus erythematosus (SLE), and Rheumatoid arthritis (RA) (Jin et al., 2007). Moreover, an autoinflammatory syndrome named NAIAD syndrome has been described in these patients that present with systemic inflammation, diffuse skin

dyskeratosis, arthritis, vitamin A deficiency, high transitional B-cell levels, neutrophilia, decreased number of T-cells, and dramatically increased serum IL-18 and caspase-1 (Grandemange et al., 2017). Precancerous manifestations including multiple self-healing palmoplantar carcinoma (MSPC), familial keratosis lichenoides chronica (FKLC), and inherited corneal intraepithelial dyskeratosis were also detected (Alehashemi and Goldbach-Mansky, 2020; Drutman et al., 2019). The reason for the higher susceptibility of the skin to these manifestations is the high level of NLRP1 expression in keratinocytes (Zhong et al., 2016). Reported infections in these patients include mucocutaneous candidiasis and *Giardia intestinalis* (Grandemange et al., 2017). IL-1 blockade for treating systemic features and retinoic acid and vitamin A for the treatment of skin manifestations are the therapeutic strategies (Grandemange et al., 2017).

NLR4 deficiency

Pathogenesis and etiology

NLR4-related gain of function mutations are characterized by autoinflammation and infantile enterocolitis (AIFEC) (Canna et al., 2014; Romberg et al., 2014), NOMID-like symptoms, and macrophage activation syndrome (MAS)-like symptoms with cytotoxic T-cell dysfunction, IFN γ -related hemophagocytosis, and myeloid cell activation (Romberg et al., 2017).

Clinical perspective

Patients may display increased IL-18 serum levels and IL-18/CXCL9 ratio (Romberg et al., 2017). A study has reported clinical improvement in an infant patient with MAS and enterocolitis after treatment with recombinant human IL-18 binding protein. The patient had been resistant to IL-1 blockade, corticosteroids, and anti-TNF- α treatment (Canna et al., 2017). Anakinra may be useful in the treatment of NOMID-like symptoms; however, it was not shown effective enough in alleviating AIFEC flares (Romberg et al., 2017).

Mendelian susceptibility to mycobacterial diseases-causing defects

Pathogenesis and etiology

The IFN γ -mediated immunity is an integral part of host defense in controlling mycobacterial infections. Recognition of mycobacterial microorganisms by PRRs leads to the secretion of cytokines including ISG15, IL-12, and IL-23 that further bind to their receptors on T-helper and NK cells. IL-12R consists of IL-12R β 1 and IL-12R β 2 chains (Rosenzweig and Holland, 2005). Their cooperation with Tyk2 and Jak2 kinases and promotion of signal transducer and activator of transcription-4 (STAT4) ultimately lead to IFN- γ induction (Watford et al., 2003). Moreover, this pathway produces IL-17 and TNF- α that contribute to the initiation of adaptive immune responses by promoting differentiation of naïve T-helper cells toward an antigen-specific T-helper type 1 (Th1) (Mahdaviyani et al., 2020). Coordination between mononuclear phagocytes of the innate immunity and T cells of the adaptive immunity plays a crucial role in defense against mycobacteria. Additionally, when IFN- γ binds to its receptor, IFN- γ R, on macrophages, it induces IFN- γ production via association with Jak1 and Jak2 and STAT1 (Casanova and Abel, 2002). This IFN- γ enhances the ability of macrophages to phagocytose and confine mycobacteria through some mechanisms, including granuloma formation (Parvaneh et al., 2008).

Immune responses against invading mycobacteria heavily depend on the function of IL-12 and IFN- γ . The identification of IL-12R β 2 and IL-23R deficiencies and their association with infections have shed more light on the importance of IL-12- and IL-23-dependent IFN- γ immunity for resistance against mycobacteria (Bustamante, 2020). Mendelian susceptibility to mycobacterial diseases (MSMD) is a condition caused by inherited defects in IFN- γ immunity that predispose patients to infections with weakly virulent mycobacteria. They include environmental mycobacteria and substrains of the BCG vaccine.

A number of germline mutations, either autosomal or X-linked, have been identified in MSMD patients. These genes include IFNGR1, IFNGR2, STAT1, IL12B, IL12RB1, IL12RB2, SPPL2A, IL23R, ISG15, NEMO, and CYBB. SPPL2A, TYK2, JAK1, and ROR γ /ROR γ T at the molecular level and IFN- γ -producing Th1 and $\gamma\delta$ T cells at the cellular level are the newest discovered genetic defects contributing to MSMD symptoms (Rosain et al., 2019). TYK2 defects share some characteristics with IFN- γ signaling defects, though they are not categorized as classical MSMD genetic defects (Parvaneh et al., 2008). IFNGR1 mutations that can be recessive or dominant were the first described genetic defects in association with MSMD (Jouanguy et al., 1996). Genetic defects of IL-12R β 1 and IFN γ R1 are the most common etiologies of MSMD (Mahdaviyani et al., 2020). IL12B defect is known as the single cytokine gene defect leading to PID (Parvaneh et al., 2008). STAT1 deficiency can be heterozygous or homozygous with more severe outcomes.

Next-generation sequencing is a useful technique for genetic diagnosis, especially in patients whose diagnosis has not yet been defined.

Clinical perspective

As mentioned before, MSMD patients are susceptible to weakly virulent non-tuberculous mycobacteria, including *M. bovis* and *M. avium*. *M. avium* may be present at infection sites like teeth without causing much harm (Parvaneh et al., 2008). They are also susceptible to the more virulent but less frequent *M. tuberculosis* (Ozbek et al., 2005). Mycobacterial infections, beginning in early childhood, present with a wide range of manifestations that can be localized or disseminated and may reoccur (Cottle, 2011; Bustamante et al., 2014). In addition to mycobacteria, Patients have presented with systemic non-typhoidal or typhoidal

Salmonella serotypes. Other infections comprise parasites such as leishmaniasis and toxoplasmosis, intramacrophagic bacteria such as listeriosis and klebsiellosis, fungi such as histoplasmosis, CMC, and viruses, such as CMV and human herpesvirus 8 (HHV-8) (Mahdavian et al., 2020; Camcioglu et al., 2004; Ouederni et al., 2014). TYK2-deficient patients may display disseminated BCG, recurrent HSV-1, and molluscum contagiosum skin infections (Jouanguy et al., 2007).

IFN- γ therapy combined with antibiotic therapy constitutes the main therapeutic strategy in MSMD patients. Recessive complete forms of IFN- γ deficiency have a poor prognosis, and their responses to subcutaneous administration of IFN- γ are not favorable (Dorman et al., 2004). However, IFN- α therapy has shown more positive outcomes (Ward et al., 2007). Also, HSCT may be helpful though graft rejection is probable (Chantraine et al., 2006). On the other hand, recessive partial forms of the disease respond well to antimycobacterial prophylaxis, subcutaneous administration of IFN- γ , and tailored antibiotic therapy in case of an ongoing infection (Haverkamp et al., 2006). Likewise, IL12B/IL12RB1- deficient patients demonstrate a favorable response to antibiotics and IFN- γ (Parvaneh et al., 2008).

WHIM syndrome-causing defects

Pathogenesis and etiology

WHIM syndrome is the first identified chemokine receptor-dependent PID and consists of Warts, Hypogammaglobulinemia, Infections, and Myelokathexis. Myelokathexis is a condition caused by the accumulation of mature neutrophils in the bone marrow that leads to neutropenia. WHIM-causing genetic defects are traced back to mutations of G protein-coupled chemokine receptor CXCR4 (Hernandez et al., 2003). CXCR4, expressed in the immune system and the CNS, is central for homing of cells in the bone marrow. A gain of function and usually autosomal dominant mutation in this gene causes pathological holding of cells within the bone marrow.

Clinical perspective

The most important clinical manifestation of germline gain-of-function CXCR4 mutation is HPV-induced uncontrolled lesions and warts. Also, benign bacterial infections with a good remission after antibiotic therapy may occur in these patients. However, patients with considerable neutropenia rarely suffer from invasive bacterial infections (Gulino, 2003; Diaz, 2005). Opportunistic infections are not common in CD4⁺ T lymphopenia patients, except HPV (Heusinkveld et al., 2019). Epstein-Barr virus (EBV)—induced lymphoma affecting the skin and gut, and infrequent complex congenital heart defects were reported in these patients (Imashuku et al., 2002; Chae et al., 2001; Gulino, 2003).

Myelokathexis is almost always observed in these patients. Mild thrombocytopenia, Hypogammaglobulinemia, reduced number of CD27⁺ B cells, neutropenia, monocytopenia, and lymphopenia have also been described (Heusinkveld et al., 2019; Gulino et al., 2004).

Measures for the management of WHIM syndrome patients include laser ablation of warts, close monitoring of genital warts, antibiotic therapy for recurrent infections, HSCT with favorable results in complete clinical cure of the patients, and granulocyte colony-stimulating factor (G-CSF) and GM-CSF for increasing neutrophil count (Parvaneh et al., 2008). Inactivated vaccines are not contraindicated, while live vaccinations should be administered after assessing potential risks according to the patient's condition (Heusinkveld et al., 2019).

Epidermodysplasia verruciformis-causing defects

Pathogenesis and etiology

Epidermodysplasia verruciformis (EV) is an inherited rare genodermatosis that heightens the susceptibility of patients toward HPV infection and cutaneous malignancies, especially cutaneous squamous cell cancer (SCC). EV is a heterogeneous autosomal recessive disorder with mutations in EVER1 and EVER2 genes, also called transmembrane channel-like (TMC) 6 and TMC8. It was the first identified disease to link viral infections to cancers in humans (Burger and Itin, 2014). A classification has been proposed that categorizes types of EV in three classic genetic, nonclassic genetic, and acquired EV classes (Huang et al., 2018).

Clinical perspective

Clinical manifestations of EV begin to appear in early childhood and infancy. Patients usually display verrucae planae-like lesions on the extremities or pityriasis versicolor-like lesions on the trunk with mild acanthosis and hyperkeratosis (Burger and Itin, 2014). They are at increased risk of developing precancerous skin lesions in sun/UV-exposed parts of the body during the second or third decade of life that may transform to skin cancers, usually after the second decade of life (Lutzner, 1978; De Oliveira et al., 2003). In spite of the fact that these cancers progress slowly, the risk of their destructive extension and metastasis exists (Lutzner et al., 1984). Mucous membranes are not commonly involved in developing these lesions. Being susceptible and often infected with HPVs, especially HPV types 5 and 8, patients demonstrate increased serum antibody reactivity against β -HPVs (Michael et al., 2010).

The treatment consensus of EV patients is mainly comprised of symptomatic therapies and sun avoidance advice immediately after the disease is diagnosed. The first line measure toward precancerous lesions is cryotherapy. Surgical removal is beneficial in the case of localized aggressive SCC (Gubinelli et al., 2003). Finally, topical treatment with imiquimod, retinoids, 5-interferon, fluorouracil, and tacalcitol is recommended for EV treatment (Burger and Itin, 2014).

Introduction

The innate immunity is the most evolutionarily conserved arm of the immune system and the first line of defense against invading pathogens. Innate immune responses are not specific to any antigen and are carried by cells such as macrophages, NK cells, neutrophils, mast cells, dendritic cells, and innate-like lymphocytes. It is only in the past two decades that monogenic diseases of aberrant activation of the innate immunity has been recognized, and they are referred to as Systemic Autoinflammatory Disorders (SAIDs) (Manthiram et al., 2017; Aksentijevich et al., 2020). Originally, the concept of *autoinflammation* was introduced to denote that the inflammatory phenotype in these patients is predominantly driven by myeloid cells. However, as innate and adaptive immunity are closely intersected, cells of the adaptive immune system may eventually become dysregulated by overactivated myeloid cells. Subsequently, the boundaries of what defines a systemic autoinflammatory condition have expanded to include features of immunodeficiency, autoimmunity, and atopy (Tangye et al., 2020). In particular, several of these diseases manifest with a prominent B-cell deficiency. SAIDs have been linked to germline and somatic pathogenic variants in over 40 genes (Aksentijevich and Schnappauf, 2021). They are caused by defects in the cytosolic sensors, cytokine receptors, proteasome-mediated protein degradation, protein misfolding, lipid metabolism, and ubiquitylation. The molecular classification has become challenging as many mutated proteins converge to upregulate common inflammatory pathways, NF- κ B, IL-1, and interferons (Savic et al., 2020). This chapter will attempt to categorize diseases based on the function of mutated protein and discuss associated pathogenic variants, clinical presentation, and therapeutic management of patients with SAIDs (Tables 1 and 2).

Inflammasome-mediated autoinflammatory diseases

Inflammasomes are cytosolic sensors that have emerged as important regulators of innate immune responses (de Vasconcelos and Lamkanfi, 2020). They can sense various exogenous and endogenous ligands known as pathogen and danger-associated molecular patterns (PAMPS) and DAMPS (e.g., cytosolic nucleic acids, crystalline particles). *Inflammasomes* function in the form of multi-protein complexes that upon its activation cause caspase-1 mediated cleavage of the IL-1 family of proinflammatory cytokines. Besides, activated caspase-1 also cleaves gasdermin D, whose N-terminal cleavage product forms pores in the cell membrane, causing pyroptosis, a type of inflammatory cell death. Most inflammasomes are nucleated by proteins that belong to the family of nucleotide-binding leucine-rich repeat-containing receptors (NLR). Via its N-terminal pyrin domain (PYD) or a CARD domain, these proteins bind to the adaptor protein, apoptosis-associated speck-like protein with a caspase recruitment domain (ASC), which subsequently cause activation of caspase-1. The pyrin inflammasome is the only functionally characterized inflammasome nucleated by the structurally different protein, although it comprises an N-terminal PYD. Pyrin is a unique intracellular sensor because it does not recognize and bind pathogen-derived antigens directly. Rather it is activated in response to pathogen-associated virulence factors, generated through bacterial toxin-induced inactivation of host GTPase RhoA proteins.

Erroneous activation of the inflammasomes can lead to diseases that are known as *inflammasomopathies* (Alehashemi and Goldbach-Mansky, 2020). Nearly all of these conditions are caused by heterozygous gain-of-function mutations in the centrally located NACHT domain of these proteins, which lead to a variable degree of activation of the respective inflammasome. Patients with the most severe phenotypes carry a *de novo* pathogenic variant that results in constitutive inflammasome activation. A milder disease-associated mutation may affect the function of the autoinhibitory domain or protein stability. Other environmental factors such as cold temperature, heat, physical or emotional stress can facilitate inflammasome activation. Variability in clinical presentations can be explained by cell or tissue expression of the mutated protein. Most inflammasomes are highly expressed in hematopoietic cells, particularly myeloid cells. Patients who carry pathogenic variants in the pyrin, NLRP3, and NLRP12 inflammasomes present with a constellation of features that include chronic or recurrent fever, skin rash, arthralgia/arthritis, and in severe cases, CNS inflammation. As the NLRP1 inflammasome is highly expressed in epithelial cells, the linked disease phenotype manifest with hyperplastic dyskeratosis and susceptibility to skin cancers. The NLRC4 inflammasome is highly expressed in intestinal epithelial cells, where it restricts replication of Gram-negative bacteria, and the associated phenotype includes gastrointestinal inflammation (Duncan and Canna, 2018). The common feature of *inflammasomopathies* is an excessive release of IL-1 β , and that they are highly responsive to therapies with IL-1 inhibitors (De Benedetti et al., 2018).

	JAK 1&2-Ruxolitinib JAK1&3-Baricitinib, Tofacitinib		PRAAS/CANDLE USP18, ISG15 APLAID, HA20

NLRP1-associated autoinflammatory diseases (MSPC/FKLC/NAIAD)

NLRP1 pathogenic variants can be inherited in a dominant or recessive manner, depending on their position in the affected protein domain. They are linked to a spectrum of phenotypes from systemic inflammation and arthritis to non-inflammatory skin disease. Skin manifestations include hyperplastic dyskeratosis, upper respiratory tract papillomatosis and susceptibility to malignant squamous cell carcinoma (SCC) and multiple self-healing palmoplantar carcinoma (MSPC) (Zhong et al., 2016; Drutman et al., 2019). Mutant primary keratinocytes have increased production of proinflammatory cytokines IL-1 and IL-18. Common low-penetrance variants (SNPs) in *NLRP1* have been associated with susceptibility to vitiligo and other autoimmune and autoinflammatory diseases, however, their functional consequences need to be investigated (Jin et al., 2007).

NLRP3-associated autoinflammatory diseases (FCAS/MWS/NOMID)

Heterozygous GoF variants in *NLRP3* have been linked to a continuum of inflammatory phenotypes denoted as cryopyrin-associated periodic syndrome (CAPS) from the milder phenotype named familial cold autoinflammatory syndrome (FCAS), to Muckle-Wells syndrome (MWS), and most severe neonatal-onset multisystem inflammatory disease (NOMID; also known as CINCA) (Booshehri and Hoffman, 2019). While features of fevers, urticaria-like rash, and joint involvement are shared among all three disease entities, patients with MWS/NOMID can develop CNS inflammation and bony overgrowth. The most common CNS manifestations are sensorineural hearing loss, vision loss, and aseptic meningitis that can result in cognitive impairment. Systemic inflammation in NOMID/CINCA is chronic and almost persistent, whereas in patients with FCAS flares are triggered by cold temperature. Systemic A amyloidosis (SAA) has been reported in patients with a severe phenotype.

CAPS-associated variants can be inherited as germline or somatic mutations. Identification of a de novo variant in *NLRP3* is consistent with the diagnosis of NOMID/CINCA. Somatic (post-embryonic) variants originating in the myeloid lineage have been identified in about 30% of patients with classical CAPS or with late-onset CAPS (Louvrier et al., 2020). Testing for somatic variants may require the use of next-generation sequencing-based diagnostic methods. Low-penetrance variants, Val198Met (Val200Met), Lys488Arg (Lys490Arg), and Gln703Lys (Gln705Lys) have been linked to a childhood autoinflammatory disease PFAPA (periodic fever, aphthous stomatitis, pharyngitis, adenitis), adult-onset disease Schnitzler syndrome, and other inflammatory phenotypes.

The clinical significance of these variants remains unclear. Activating mutations in NLRP3 cause caspase-1 mediated excessive production of IL-1 β , and CAPS prognosis has been dramatically changed with the use of IL-1 inhibitors.

NLRP12-associated (FCAS/MWS/NOMID) diseases (FCAS2)

NLRP12 is highly expressed in hematopoietic cells, however, it is unclear whether it forms a functional inflammasome. NLRP12 may function as an inhibitory protein by suppressing inflammatory responses in activated myeloid cells. Heterozygous LoF mutations in *NLRP12* are reported in several families with dominantly inherited cold-induced fever, localized or generalized urticaria-like rash, myalgia, and headaches (Borghini et al., 2011). The onset of symptoms is typically in childhood and avoiding exposure to cold temperatures prevents the disease flare. Given that NLRP12 is an anti-inflammatory protein, haploinsufficiency is the proposed mechanism of the disease that is yet to be characterized. Patient monocytes spontaneously secrete IL-1 β cytokine however, the efficacy of IL-1 inhibitors has been limited.

NLR4-associated autoinflammatory diseases (MAS/FCAS-4)

Heterozygous pathogenic missense variants in *NLR4* are gain-of-function, and they have different effects on the protein function, which ultimately influence disease severity. Severe de novo inherited disease-associated mutations spontaneously activate the protein and can cause life-threatening enterocolitis or a potentially lethal macrophage activation syndrome (MAS) (Canna et al., 2014; Romberg et al., 2014). The gastrointestinal inflammation can be very severe, particularly in infancy, however, some patients can survive the initial GI insult to develop a chronic milder GI disease. It is thought that the gut microbiota plays an important role in the expressivity of GI inflammation. Milder pathogenic variants that reduce the threshold for protein activation have been linked to a dominantly inherited phenotype with FCAS-like features. Primary patient myeloid cells spontaneously secrete IL-1 β and IL-18 cytokines. Patients with milder disease respond well to anti-IL-1 therapy, while patients with severe phenotype require aggressive treatment. New biological therapies with recombinant IL-18 binding protein (IL-18 BP), or blockade of interferon γ have shown promising results (Canna et al., 2017).

Pyrin-associated autoinflammatory diseases

Familial Mediterranean fever (FMF)

Pathogenic variants in pyrin, encoded by *MEFV*, have been associated with the most common autoinflammatory disease, familial Mediterranean fever (FMF), which has a high prevalence in eastern Mediterranean populations including, Arabs, Armenians, Iranians, Jews, and Turks. FMF is characterized by recurrent episodes of short-lasting fever accompanied by severe abdominal and/or chest pain, monoarthritis, and erysipelas-like erythematous rash. SAA amyloidosis is the most severe complication of the disease and was a major cause of mortality before colchicine therapy. FMF is caused by recessively inherited biallelic pathogenic missense variants that reside almost exclusively in the C-terminal the B30.2/SPRY domain, encoded by exon 10. Despite its recessive inheritance, FMF variants act as gain-of-function alleles by reducing a threshold for the activation of the pyrin inflammasome (Schnappauf et al., 2019).

Pathogenic mutations in other domains of pyrin have been associated with dominantly inherited severe inflammatory phenotypes. These pathogenic variants activate the pyrin inflammasome either by preventing pyrin inhibition or by enhancing its oligomerization. Heterozygous pathogenic variants in exon 2 are linked to a distinct disease, named pyrin-associated autoinflammation with neutrophilic dermatosis (PAAND), manifesting with severe skin inflammation, polyarthralgia, and longer-lasting episodes of fever. Monocytes from PAAND patients produce higher levels of interleukin IL-1 β and IL-18 compared to cells from FMF patients. Dominantly inherited variants in exons 5–8 have been linked to severe colchicine-resistant fever syndrome manifesting with longer episodes of fever, serositis, severe polyarticular migratory arthritis, and renal SAA amyloidosis. The clinical significance of low-penetrance variants, Glu148Gln and Pro369Ser/Arg408Gln is still debated, although these variants may act as susceptibility alleles to inflammation (Gattorno et al., 2009; Berkun et al., 2011; Taniuchi et al., 2013; Batu et al., 2016). Most FMF patients have an excellent response to treatment with colchicine, while patients with more severe phenotype and/or amyloidosis require therapy with IL-1 inhibitors (Sag et al., 2020).

Diseases of cytoskeletal dysregulation/inflammatory actinopathies

The actin cytoskeleton is a dynamic network of actin and actin-binding proteins that are indispensable for many cellular functions, including, cell division, cell morphology, cell motility, intracellular trafficking, and endocytosis. Proteins that regulate actin polymers' assembly and organization, have been implicated in the pathogenesis of primary immunodeficiencies and autoinflammatory diseases, which corroborate the importance of actin cytoskeleton in modulating immune responses (Tangye et al., 2019).

The actin related protein complex (ARP) 2/3 is essential for the assembly and branching of actin polymers. Wiskott-Aldrich syndrome protein (WASP) is one of many regulatory proteins that promotes activation of the Arp2/3 complex. Besides, the WASP function is regulated by several proteins including, WIP (WASP-interacting protein), PSTPIP1 (proline serine threonine

phosphatase-interacting protein 1), and CDC42 (cell division cycle 42). Loss of WASP is associated with a severe X-linked disease (WAS) that manifests with immunodeficiency, thrombocytopenia, and autoimmunity. PSTPIP1 is thought to negatively regulate WASP by permitting PTP-PEST-mediated dephosphorylation of WASP. CDC42 is a member of the Rho GTPase family of proteins that induces activation of WASP to enable the interaction with the ARP2/3 complex. The Nck-associated protein 1-like (NCKAP1L/HEM1) is required for the RAC-mediated stabilization and activation of the WASP-family verprolin-homologous protein (WAVE2) complex. WAVE2's function is similar to WASP in allowing the ARP2/3 complex to initiate actin polymerization.

WD-repeat protein 1 (WDR1), also known as actin-depolymerizing factor (ADF/AIP1), is critical for the reorganization of the actin cytoskeleton by inducing disassembly of actin filaments. Abnormalities in the actin cytoskeleton organization affect the differentiation and function of innate and adaptive immune cells.

Pyogenic arthritis pyoderma gangrenosum and acne (PAPA) syndrome (PAPA)

Heterozygous pathogenic missense variants in *PSTPIP1* are associated with a severe type of neutrophilic dermatosis named pyogenic arthritis pyoderma gangrenosum and acne (PAPA) syndrome. PAPA usually present in childhood with sterile arthritis, while skin inflammation often starts in puberty and can be triggered by minor injuries. The most common PAPA-associated mutations, Ala230Thr and Glu250Gln, act by reducing the affinity for PTP-PEST and increasing the affinity of PSTPIP1 to pyrin. This finding suggests that inflammation in PAPA patients is partially due to an increased pyrin inflammasome activity and heightened IL-1 β production. Patients with severe mutations, Glu250Lys and Glu257Lys, have a more severe phenotype with abnormalities in the bone marrow and hematological manifestations (Belelli et al., 2017). This phenotype is named hyperzincemia and hypercalprotecinemia (Hz/Hc) or PSTPIP1-associated myeloid-related proteinemia inflammatory syndrome (PAMI) (Holzinger et al., 2015). PAPA patients with joint and mild skin inflammation respond well to treatment with IL-1 inhibitors, while patients with pyoderma gangrenosum require a higher dose of biologics (Omenetti et al., 2016; Mistry et al., 2018). HSCT has been successful in several PAMI patients resistant to medical therapies (Laberko et al., 2021).

Periodic fever, immunodeficiency, and thrombocytopenia syndrome (PFITS)

PFITS is a recessively inherited disease caused by LoF mutations in *WDR1*, which cause an impairment in the actin depolymerization. PFITS patients present with recurrent invasive opportunistic infections, periodic fevers, severe stomatitis, thrombocytopenia, impaired wound healing, pyoderma gangrenosum, and acne. Growth failure, dysmorphic face, and neurological impairment are seen in patients who have nearly absent protein function. WDR1-deficient myeloid cells produce exceedingly high levels of IL-18 cytokine, while interestingly the IL-1 β cytokine production is not affected. Treatment modalities for PFITS include immunoglobulin replacement, antibiotic prophylaxis, and IL-18 blockade (Kuhns et al., 2016; Standing et al., 2017; Pfajfer et al., 2018; Seppanen, 2018).

ARPC1B deficiency

Biallelic LoF mutations in the ARPC1B subunit of the ARP2/3 complex have been identified in patients who present with an early-onset immunodeficiency and low platelet count, similar to the Wiskott-Aldrich syndrome (Kahr et al., 2017; Brigida et al., 2018; Volpi et al., 2019; Randzavola et al., 2019). Other disease features include failure to thrive, small vessel vasculitis, early onset eczema, and inflammatory bowel disease. The platelets are small and deficient in dense granules and lamellipodia. The immune phenotype is characterized by eosinophilia, auto-antibody production, elevated IgE and IgA levels, and T-cell lymphopenia. Clinically, patients are predisposed to severe bacterial and viral infections. Treatment is symptomatic.

CDC42 deficiency

Dominantly inherited LoF mutations in the ubiquitously expressed isoform of cell division cycle 42 (CDC42) cause a neurodevelopmental phenotype, while inactivating mutations in the transcript isoform highly expressed in hematopoietic cells has been identified in patients with a severe potentially fatal hematological disease named NOCARH (neonatal onset of pancytopenia, autoinflammation, rash, and hemophagocytosis) (Lam et al., 2019; Gernez et al., 2019). Mutated protein displays an aberrant subcellular localization and rearrangement in actin cytoskeleton that affects all hematopoietic cells' function. BM mononuclear cells spontaneously release IL-1 β and IL-18 cytokines, while high levels of CXCL9 and IFN- γ are found during HLH episodes. Treatment with a monoclonal antibody targeting IFN- γ was successful in one patient, while some patients responded to IL-1 therapy.

NCKAP1L/HEM1 deficiency

Pathogenic biallelic LOF variants in HEM1 disrupt activation of the WAVE complex and lead to a complex immune dysregulation with features of immunodeficiency, lymphoproliferation, atopy, and severe inflammation (Cook et al., 2020; Castro et al., 2020). Deficiency of WAVE activity results in defective F-actin polymerization, besides, mutant HEM1 protein is shown to abrogate mTORC2-mediated activation of the AKT signaling pathway. Treatment is symptomatic.

Diseases of dysregulated ubiquitination

Ubiquitylation is a type of post-translational reversible protein modification that is critical for regulating all biological processes, including immune responses. Ubiquitylation involves the attachment of highly conserved 76-aa ubiquitin (Ub) molecules to target proteins in the form of a monomer or polymers (Ub chains). The type of linkage connecting the monomers in Ub chains ultimately determines the function of the modified protein. The attachment of Lys63 and Linear (Met1) Ub chains stabilize and upregulate protein activity, while the attachment of Lys48 Ub chains tags proteins for proteasomal degradation. The ubiquitylation process is counter regulated by a class of enzymes known as deubiquitinases (DUBs), and they have cell and target-specific functions.

The attachment of Met1 Ub chains to various immune molecules by the LUBAC (Linear Ubiquitin Chain Assembly Complex) is important for the assembly of receptor signaling complexes, for instance, TNFR1, TLRs, and IL-1R. LUBAC function is counteracted by OTULIN, a highly conserved deubiquitinase, with a specific activity to hydrolase Met1-linked Ub chains from target proteins (Shimizu et al., 2015). TNFAIP3, also referred to as A20, is another ubiquitin-editing enzyme that removes K-63 Ub polymers and facilitates the addition of K48 Ub to various target molecules. Thus, both OTULIN and A20 operate as negative regulators of the NF- κ B pathway. Defect in DUB activity affects other inflammatory pathways as well. In the past few years, several autoinflammatory diseases have been explained by dysregulation in the ubiquitin signaling pathway (Aksentjevich and Zhou, 2017; Beck et al., 2020).

Linear Ubiquitin Chain Assembly Complex (LUBAC) deficiencies

LUBAC consists of the catalytic subunit HOIP (HOIL1 interacting protein; *RNF31*) and two accessory proteins: HOIL-1 (Heme-oxidized IRP2 Ubiquitin ligase 1; *RBCK1*) and SHARPIN (SHANK-interacting protein like 1; *SIPL1*). Defect in one subunit of LUBAC destabilizes the expression of the whole LUBAC complex. LUBAC depletion leads to attenuation of NF- κ B and other inflammatory pathways. LUBAC activity is also important for proper B and T cell development, and maintenance of adaptive immune responses.

HOIL-1 and HOIP deficiencies are recessively inherited diseases caused by biallelic LoF mutations in respective proteins (Boisson et al., 2012, 2015; Oda et al., 2019). LUBAC-deficient patients have compromised immune responses and suffer from recurrent invasive bacterial infections. In addition to immunodeficiency, they present with systemic inflammation manifesting with fevers and GI inflammation. LUBAC-deficient patients are predisposed to develop muscular weakness and cardiomyopathy that is potentially life-threatening due to amylopectin deposition. Milder pathogenic mutations may cause an early-onset progressive myopathy/cardiomyopathy without overt immunodeficiency (Nilsson et al., 2013). Treatment is symptomatic.

Haploinsufficiency of A20 (HA20)

Heterozygous germline LoF variants in *TNFAIP3* cause a childhood-onset disease with a constellation of features from autoinflammation to autoimmunity (Zhou et al., 2016a). Typical signs include early-onset fevers, mucocutaneous ulcers, gastrointestinal and eye inflammation, arthralgia, lymphadenopathy, and a wide range of autoimmune findings (Aeschlimann et al., 2018; Berteau et al., 2018; Lawless et al., 2018; Kadowaki et al., 2018). A defect in HA20 function results in increased activity in the canonical NF- κ B pathway. During flares, high levels of many proinflammatory cytokines and chemokines are found in blood samples. Treatment with cytokine inhibitors especially TNF inhibitors and JAK inhibitors are efficacious in controlling systemic inflammation (Schwartz et al., 2020). HSC transplantation has been successful in one patient (Duncan et al., 2018). Common variants in the *TNFAIP3* gene locus, SNPs, have been linked with susceptibility to many autoimmune diseases, including systemic lupus erythematosus, rheumatoid arthritis, Crohn's disease, systemic sclerosis, psoriasis. Somatic variants in *TNFAIP3* are found in patients with Hodgkin's lymphoma and B cell lymphomas.

Otulin deficiency/otulipenia/ORAS

Recessively inherited LoF mutations in the *OTULIN* gene have been associated with the early-onset severe inflammatory disease, named otulipenia, also known as otulin-related autoinflammatory syndrome (ORAS) (Zhou et al., 2016b; Damgaard et al., 2016). This disease is rare and reported mainly in patients from founder populations. Clinical picture comprised failure to thrive, recurrent fevers, joint swelling, GI inflammation, an erythematous rash with skin nodules, lipodystrophy. A defect in DUB activity results in excessive linear ubiquitination and constitutive activation of key molecules in the canonical NF- κ B pathway. The inflammatory signature is stronger than in many other autoinflammatory disorders and characterized by spontaneous production of many proinflammatory cytokines and chemokines. Therapy with TNF inhibitors is very effective in suppressing systemic inflammation and reducing disease morbidity and mortality. HSC transplantation has been effective in one patient (Damgaard et al., 2019).

VEXAS (vacuoles, E1, X-linked, autoinflammatory, somatic) syndrome

UBA1 is a X-linked gene that encodes the major E1 enzyme required to initiate ubiquitylation in all cellular proteins. Pathogenic somatic missense mutations at the methionine 41 amino acid residue are found to affect the protein translation of the canonical cytoplasmic isoform and to give rise to a novel, catalytically impaired protein isoform (Beck et al., 2020). Patients present with an

often-fatal syndrome in late adulthood, manifesting with fevers, vasculitis, dysplastic bone marrow, cytopenias, venous thromboembolism, chondritis, vasculitis, neutrophilic cutaneous and pulmonary inflammation, and characteristic vacuoles in common myeloid and erythroid progenitor cells. The somatic variants originate in early marrow progenitor cells, however, in peripheral blood they are found exclusively in myeloid cells at an allele frequency often higher than 50%. Mutant lymphocytes either fail to proliferate or are eliminated from peripheral blood. Mutant monocytes display decreased ubiquitylation and upregulation in cellular stress responses and highly activated inflammatory signature. Patients are refractory to treatment with multiple disease-modifying anti-rheumatologic drugs (DMARDs) and cytokine inhibitors, while glucocorticoids in high doses can ameliorate severe inflammatory symptoms.

USP18 deficiency

Ubiquitin-specific peptidase 18 (USP18) is a type I interferon response gene that functions as a negative feedback regulator. Defect in type I IFN negative regulation leads to persistently high IFN-1 activity. Patients with biallelic LoF pathogenic variants in USP18 present at birth with a pseudo-TORCH-like phenotype, which resembles sequelae of congenital infections. Clinical signs include systemic inflammation, polymicrogyria, brain calcifications, seizures, liver dysfunction, severe thrombocytopenia, petechiae, necrotizing skin lesions, and respiratory failure (Meuwissen et al., 2016; Martin-Fernandez et al., 2020). The disease is lethal if left untreated. JAK inhibitor ruxolitinib was used successfully in one patient to induce sustained suppression of the disease activity (Alsohime et al., 2020).

ISG15 deficiency

ISG15 is a ubiquitin-like molecule with two functions; free intracellular ISG15 is crucial for USP18-mediated downregulation of type I IFN-signaling, while free extracellular ISG15 is crucial in IFN- γ -dependent antimycobacterial immunity (Hermann and Bogunovic, 2017). ISG15 expression is induced by type I interferons to stabilize the USP18 protein, thus the loss of ISG15 results in lower levels of USP18 and less efficient inhibition of type I IFN signaling. Patients with ISG15 deficiency have a relatively mild inflammatory phenotype with enhanced peripheral blood interferon gene expression signature, however, they may be predisposed to develop brain calcifications and neurological abnormalities (Bogunovic et al., 2012). Some patients present with a clinical disease only in response to BCG vaccination as the result of insufficient ISG15-dependent interferon- γ production.

Diseases mediated by activated NF- κ B pathway

Multitude of cellular processes converge at the point of NF- κ B, transcription factor (TF), activation. NF- κ B is a protein complex made up of five different members that combine to create homo- and hetero-dimers and exert wide range of biological effects. Activation of NF- κ B is critical for differentiation of immune cells, propagation of inflammatory response, and maintenance of cell viability. There is a number of monogenic disorders linked to dysregulation in activity of NF- κ B pathway, and the associated phenotypes are often mixed, having both features of autoinflammation and immunodeficiency (Schnappauf and Aksentijevich, 2020).

RIPK1-associated diseases

Receptor-interacting serine/threonine-protein kinase 1 (RIPK1) has a critical role in a range of cellular functions, including the TNF signaling pathway. RIPK1 interacts with a variety of adaptors, ubiquitin ligases and kinases, to regulate not only pro-inflammatory effects but also cell survival.

Biallelic LoF variants in *RIPK1* have been described in patients who present with a combination of features comprising immunodeficiency, arthritis, and gastrointestinal inflammations (Cuchet-Lourenco et al., 2018; Li et al., 2019). RIPK1-deficient cells display compromised NF- κ B activity, decreased production of proinflammatory cytokines, and are hypersensitive to cell death by necroptosis. The inflammatory phenotype might be explained by the NLRP3 inflammasome activation and increased IL-1 β production. Successful HSCT has been reported; however, the intrinsic intestinal phenotype may not be rescued.

In contrast, patients with heterozygous activating pathogenic variants that affect the residue critical for the cleavage and inactivation of RIPK1 by caspase-8, the Asp (D) 342, present with systemic inflammation and without immunodeficiency (Tao et al., 2020; Lalaoui et al., 2020). This condition was named Cleavage-resistant RIPK1-induced Autoinflammatory (CRIA) syndrome. The main features of disease are high fevers, splenomegaly, lymphadenopathy, oral ulceration. Patients respond well to targeted therapy with IL-6 inhibitors.

Blau syndrome/NOD2-associated granulomatous disease

NOD2 is an intracellular pattern recognition receptor which is able to recognize specific PAMPs, such as muramyl dipeptide (MDP), and to consequently activate NF- κ B signaling pathway.

Heterozygous GoF germline or somatic mutations in the central NACHT domain cause a severe autoinflammatory disorder termed Blau Syndrome (BS) (Miceli-Richard et al., 2001; de Inocencio et al., 2015; Mensa-Vilaro et al., 2016). BS is characterized with a triad of early-onset inflammatory granulomatous polyarthritis, dermatitis and panuveitis (Rose et al., 2015). The arthritis is fairly severe leading to contractures and camptodactyly. Up to 42% of patients with BS report moderate to severe visual impairment (Sarens et al., 2018), which involves both the anterior (iridocyclitis) and posterior (retinal vasculitis, vitritis, and choroiditis) chambers of the eye. Other organs are affected at variable degrees of inflammation. The treatment of BS remains difficult. Anti-TNF treatments combined with methotrexate are largely effective for joint and visceral complications (Milman et al., 2006). The treatment of eye inflammation is more challenging since the response to anti-TNF is not universal. Other cytokine inhibitors, IL-1 or IL-6 blockade, might also be effective.

RELA haploinsufficiency

RelA (p65), encoded by *RELA* is one of the five members of NF- κ B family, which typically forms a heterodimer with NF- κ B1 (p50). Pathogenic variants in this gene are dominantly inherited and act by the mechanism of haploinsufficiency (Badran et al., 2017). Despite impaired NF- κ B activation in response to TNF, the affected patients presented with a childhood-onset inflammatory disease manifesting with fevers, mouth ulceration, vomiting, acute ileitis, and elevated inflammatory markers. These symptoms are explained by increased susceptibility of mutant cells to TNF-induced apoptosis. A second case of ReLA haploinsufficiency was reported to have a very different phenotype consistent with autoimmune lymphoproliferative syndrome, cytopenia, recurrent aseptic meningitis, and splenomegaly. Interestingly, investigations of the patient's fibroblasts showed a propensity to apoptosis, thus it has been postulated that the ReLA haploinsufficiency results from compromised stromal and epithelial cell recovery following a mucosal injury and TNF release from the injured mucosa. The positive effects of anti-TNF therapy in this case (infliximab) supports this explanation (Comrie et al., 2018).

CARD14-associated psoriasis (CAMPS)

Caspase recruitment domain-containing protein 14 (CARD14), has a specific role in controlling activation within the skin. Here, CARD14 participates in dectin-1 and IL-17 receptors initiated signaling pathways to regulate local expression of NF- κ B-inducible cytokines and chemokines.

Heterozygous high impact GoF mutations in the *CARD14* gene that result in enhanced NF- κ B activation and upregulation of psoriasis-associated genes have been associated with a spectrum of skin inflammatory phenotypes of variable disease expressivity and penetrance. These include psoriasis vulgaris (PV), familial pityriasis rubra pilaris (PRP), and pustular psoriasis (Jordan et al., 2012b; Fuchs-Telem et al., 2012; Berki et al., 2015). Constitutional symptoms may also be present. CAMPS explains only a minority of patients with familial psoriasis. Besides, rare low-penetrance variants are reported in sporadic patients with late-onset psoriasis. Targeted sequencing of *CARD14* in seven psoriasis cohorts with over 6000 cases and 4000 controls, identified many rare missense variants at a significantly higher frequency in cases compared to controls (Jordan et al., 2012a). These variants have a variable effect on the NF- κ B activation, and it is thought that other genetic modifiers and environmental factors further influence the disease onset and expressivity. Treatment with ustekinumab, a monoclonal antibody directed against the shared p40 subunit of interleukin (IL)-12 and IL-23, has been beneficial to some patients (Eytan et al., 2014).

ROSAH

ALPK1 which stands for (alpha-kinase 1)-TIFA (TRAF-interacting protein with forkhead-associated domain) protein has recently been identified as a cytosolic innate immune receptor for bacterial ADP- β -D-manno-heptose (ADP-hep) (Zhou et al., 2018). In this role ALPK1 is able to directly bind bacterial origin ADP-hep and subsequently activate NF- κ B.

A heterozygous missense variant in *ALPK1*, Thr237Met, was identified in five unrelated families to cause retinal dystrophy, optic nerve edema, splenomegaly, anhidrosis, and migraine headache (Williams et al., 2019). Based on these most consistent clinical features the condition was named ROSAH syndrome. Although fever was not initially described, additional studies identified the same variant in patients with the PFAPA syndrome (Sangiorgi et al., 2019; Zhong et al., 2020). Collectively these findings suggest that rare variants in *ALPK1* might be contributing towards an inflammatory phenotype. It is thought that the Thr237Met variant acts as GoF by stimulating the ALPK1 kinase domain and causing activation of downstream targets in the NF- κ B signaling pathway. Elevated TNF levels were detected in both cases, and patients with ocular disease were treated with anti-TNF, however the treatment was not fully effective.

Diseases of cytokine dysregulation

The members of the IL1 family of cytokines are pivotal for promoting inflammation and as such have been implicated in the pathogenesis of many autoinflammatory diseases (Dinarello, 2018). Since they are potent mediators of inflammation, release of proinflammatory cytokines IL-1, IL-18 and IL-36 must be under tight control by anti-inflammatory members of the same family. IL-1 β is predominantly expressed in peripheral blood and bone marrow, while IL-1 α and IL-36 are highly expressed in skin.

Mechanisms that prevent active IL-1 β cytokine from triggering the signal-transducing IL-1 type I receptor include the naturally occurring IL-1 receptor antagonist (IL-1Ra) and a soluble decoy IL-1 receptor type II. Autoinflammatory diseases may arise either from gain-of-function mutations in proteins that promote IL-1 signaling or from a defect in function of inhibitory proteins. IL-1 blockade is efficacious therapy for this group of diseases (Jesus and Goldbach-Mansky, 2014).

Deficiency of IL-1 receptor antagonist (DIRA)

Patients with DIRA carry biallelic LoF mutations in the *IL1RN* gene that encodes the IL-1R antagonist protein (IL-1Ra) (Aksentijevich et al., 2009; Reddy et al., 2009). DIRA is more common in patients from founder populations. The deficiency of IL-1Ra protein leads to unrestrained IL-1 β and IL-1 α activity. Onset of disease is post-natal or in infancy and comprises severe pustular dermatitis, multifocal sterile painful osteomyelitis, and characteristic overgrowth of epiphyseal bones. Osteolytic bone lesions are typically present in long bones, vertebrae and ribs. Biopsies of inflamed skin demonstrate infiltration with MPO+ neutrophils, mostly in epidermis. The disease course is severe and accompanied by persistently high levels of acute phase reactants. DIRA patients have rapid and dramatic improvement in the skin condition upon treatment with a recombinant IL-1 receptor antagonist, anakinra.

Deficiency of IL-36 receptor antagonist (DITRA)

IL-36 subfamily of cytokines and IL-36 receptor antagonist (IL-36Ra) are highly expressed in keratinocytes. IL-36Ra prevents IL-36 cytokine mediated signaling in a similar way as IL-1Ra blocks IL-1 cytokines. Deficiency of IL-36Ra is linked to a disease manifesting with recurrent episodes of high fever, generalized pustular eruptions and erythematous scaly plaques, nail dystrophy, impetigo herpetiformis, and acral pustular lesions (Marrakchi et al., 2011; Hussain et al., 2015). Disease flares are often triggered by infections and pregnancy. Skin biopsies show dense neutrophilic, macrophage and lymphocytic infiltrates. DITRA is a recessively inherited disease, like DIRA, and most patients are identified in founder populations. Although IL-36 and IL-1 are closely related proteins, IL-1 inhibitors are not very effective in treatment of DITRA patients. Some patients experienced good response to treatment with IL12/23 targeting drugs (Bonekamp et al., 2018).

IL-10 deficiency-associated inflammatory bowel disease (EO-IBD)

IL-10 is a critical cytokine for downregulation of pro-inflammatory signals. Binding of IL-10 to its cell surface receptor induces expression of anti-inflammatory genes and decreases expression of pro-inflammatory cytokines (Engelhardt and Grimbacher, 2014). Recessively inherited LoF mutations in two genes encoding components of the IL-10 receptor (*IL10RA* and *IL10RB*) or in the gene encoding IL-10 (*IL10*) lead to early-onset inflammatory bowel disease (Glocker et al., 2009, 2010). Patients present with fevers, oral ulcers, recurrent folliculitis, severe perianal fistula, colonic abscesses, and bloody diarrhea. EO-IBD is a treatment refractory disease, and patients often require surgical interventions. HSCT is the only curative therapy (Engelhardt et al., 2013).

Diseases mediated by endoplasmic-reticulum (ER) stress

The ER stress is typically triggered by the accumulation of misfolded proteins within the ER. The resulting endoplasmic-reticulum-associated protein degradation (ERAD) and unfolded protein response (UPR) are evolutionally conserved pathways activated in the event of ER stress to maintain cell homeostasis. Through ERAD, misfolded proteins are targeted for degradation by the proteasome, whilst UPR has more diverse effects including, a reduction in protein synthesis, and ultimately activation of apoptosis in the case ER stress failed to be resolved. ER stress has other biological effects including, increased responsiveness to TLR signaling, activation of the NF- κ B pathway, and activation/phosphorylation of IRF3, a transcription factor inducing type I IFN gene expression. This section describes several autoinflammatory diseases where the interplay between ER stress, proteasome function and mROS is important for the disease pathogenesis.

Tumor necrosis factor receptor-associated periodic syndrome (TRAPS)

Heterozygous missense mutations in the *TNFRSF1A* gene, which codes for TNF receptor 1 (TNFR1), affect the structure and folding of the extracellular domain of the receptor (McDermott et al., 1999). The immunopathogenesis of TRAPS is complex with several biological pathways being implicated. A defect in TNFR1 leads to reduced levels of soluble TNFR1 that blocks binding of TNF to the cell surface. There is also evidence for ligand-independent activation of mutant TNFR1, enhanced ER stress as results of TNFR1 misfolding, increased generation of mitochondrial oxygen species, and activation of NLRP3 inflammasome (Simon et al., 2010; Bulua et al., 2011). Typical symptoms associated with TRAPS include recurrent fevers lasting for weeks, serositis, myalgia, centrifugally spreading erythematous rash, and periorbital oedema (Cudrici et al., 2020). Patients who have infrequent flares and no evidence of ongoing systemic inflammatory response can be adequately treated with on-demand therapy such as short courses of NSAIDs and/or corticosteroids. The mainstay of treatment for patients with more severe disease is with IL-1 inhibitors anakinra or canakinumab, both of which achieve rapid remission (Gattorno et al., 2008; De Benedetti et al., 2018).

Sideroblastic anemia, immunodeficiency, periodic fevers, developmental delay (SIFD)

The primary function of tRNA nucleotidyl transferase 1 (TRNT1), encoded by *TRNT1*, is catalyzing the addition of cytosine-cytosine-adenosine (CCA) trinucleotides to 3' end of all precursor tRNAs. The resulting aminoacylation enables mature tRNAs to fully participate in protein biosynthesis. In humans, TRNT1 has a non-redundant function and complete deficiency is embryonically lethal.

Patients with SIFD carry biallelic LoF variants in the *TRNT1* gene (Chakraborty et al., 2014). The principal clinical features include sideroblastic anemia, immunodeficiency, periodic fevers, neurological complications such as ataxia, seizures, sensorineural hearing loss, and developmental delay. The condition tends to present in early life, and in many cases results in multi-organ involvement and premature death (Slade et al., 2020). However, milder cases have been recognized in two families with non-syndromic retinitis pigmentosa and no other overt neurological features or cardiomyopathy (DeLuca et al., 2016). The multi-system manifestations in SIFD are not surprising considering the ubiquitous expression of TRNT1 and its critical function related to protein translation. The neurological and hematological features are most likely related to the impaired mitochondrial function; however, B cell lymphopenia/pan-hypogammaglobulinemia and systemic inflammation are more difficult to link directly to the defective TRNT1. It is thought that increased ER stress, resulting from the accumulation of damaged proteins, likely contributes to selective apoptosis in lymphocytes. The management of SIFD remains difficult and is mostly supportive with red blood cell transfusion used to correct anemia, immunoglobulin replacement in patients with immunodeficiency, and anti-TNF therapy in patients with inflammatory features (Giannelou et al., 2018). To date there is one reported case where HSCT resulted in an effective cure of the autoinflammatory phenotype (Wiseman et al., 2013).

TRAP1-associated disease

Tumor necrosis factor receptor associated protein 1 (TRAP1) belongs to the heat shock protein (HSP) 90 family. TRAP1 has a role in processing and folding of nascent and proteins damaged from cellular stress (Chien et al., 2011). TRAP1 also functions to limit mitochondrial damage and production of mROS, which can otherwise drive inflammatory innate-immune pathways.

Bi-allelic hypomorphic mutations in *TRAP1* contribute to a severe autoinflammatory disorder described in a consanguineous Pakistani family (Standing et al., 2020). The clinical phenotype of these children was complex and presented at 2 weeks of age with severe oral ulceration, recurrent fevers, failure to thrive, and persistently elevated inflammatory markers. Another unrelated case was identified with a long-standing history of the anakinra-responsive disease characterized by recurrent fevers, arthralgia, and cervical lymphadenopathy. Patients' monocytes showed increased production of mROS and a higher expression of spliced X-box protein 1 (sXBP1), which is consistent with ER stress. Lastly, LPS stimulation of PBMCs showed increased production of both IL-1 β and in particular IL-18, associated with caspase-1 activation. The disease is resistant to therapies and potentially lethal. Allogeneic HSCT was successful in a single patient.

Proteasome-associated autoinflammatory syndromes (PRAAS)

One of the main functions of the ubiquitin-proteasome system (UPS) is to catalyze the degradation of short-lived intracellular proteins. The 26S proteasome complex consists of a 20S proteolytic core and two 19S regulatory elements, and recognizes K-48 ubiquitinated proteins destined for degradation. Immunoproteasomes, which is typically found in immune cells, have standard β type subunits replaced by three inducible β -type subunits β 1i, β 2i, and β 5i.

Biallelic LoF mutations in *PSMB8*, encoding the β 5i catalytic subunit, or in other proteasomes the 20S subunits (*PSMB4*, *PSMB9*, *PSMB10*) and the proteasome chaperon (*PSMG2*) are associated with a severe autoinflammatory disorder named PRAAS or chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (CANDLE) (Agarwal et al., 2010; Arima et al., 2011; Kitamura et al., 2011; Liu et al., 2012; de Jesus et al., 2019; Sarabay et al., 2020). The genetics of PRAAS is complex and include monogenic recessive inheritance, and digenic inheritance pattern due to monoallelic mutations in two different proteasome genes (i.e., *PSMA3/PSMB8*, *PSMB4/PSMB9*, and *PSMB4/PSMB8*) (Brehm et al., 2015). Most patients present in the neonatal period or infancy. The characteristic clinical picture comprises fevers, an annular acral rash with raised edges, progressive lipodystrophy affecting the face, upper extremities, trunk, myositis, periodic fevers, and periorbital/perioral oedema. Although this disease has a chronic course, many innocuous stimuli such as viral infections, ambient cold air, and physical/psychological stress can trigger disease flares. The reduced function of the immunoproteasome is linked to upregulation in ER stress and UPR (Ebstein et al., 2019). The inflammatory signature is predominantly mediated by type I interferons, which led to the beneficial use of JAK inhibitors in this disorder (Sanchez et al., 2018).

Coatomer subunit α (COPA) syndrome

COPA syndrome is caused by dominantly inherited mutations in the *COPA* gene, which encodes the α -subunit of the coatomer complex I (COPI) (Watkin et al., 2015). COPI has a role in retrograde trafficking of cargo proteins from Golgi to the endoplasmic reticulum and within cis-Golgi compartments (Beck et al., 2009). All pathogenic mutations affect the highly conserved WD40 domain of COPA, resulting in defective protein trafficking, ER stress, and activation of the UPR and NF- κ B signaling. One such transport affected is with the STING protein (Lepelletier et al., 2020). Predictably, the clinical phenotype of affected patients is

complex (Fremond and Nathan, 2020). The COPA syndrome tends to present in childhood or early adulthood, however, the disease penetrance is incomplete and asymptomatic cases have been described. The main clinical features include interstitial lung disease, occasionally accompanied by pulmonary hemorrhage, immune-mediated kidney disease, and inflammatory arthritis. Common immunological features include the presence of autoantibodies, increased Th17 levels, and upregulation of interferon-stimulated genes (ISGs) (Volpi et al., 2018). The important role of type I IFNs in the disease pathogenesis has been further supported by two recent case reports which describe a positive response to JAK1/2 inhibition (Krutzke et al., 2019; Fremond et al., 2020).

Diseases caused by dysregulation in nucleic acid metabolism and sensing

The presence of foreign or self-nucleic acids (DNA, ssRNA or dsRNA) in the cytoplasm creates a danger signal in the cell. The mammalian cells have evolved a complex machinery to rapidly recognize and respond to the accumulation of intracellular nucleic acids. In the case of microbial invasion, one important outcome from the recognition of foreign nucleic acids is the generation of type I interferons (IFN). Although, the type I IFN is critical for an adequate immune response to infection, these powerful cytokines can cause significant host damage if left unchecked. There are several monogenic disorders, collectively termed type I interferonopathies, linked to dysregulated type I IFN signaling. These diseases result either from GoF variants in PRRs that recognize cytoplasmic nucleic acids, or from failure to remove largely self-nucleic acids (Uggenti et al., 2019).

Aicardi-Goutières syndrome (AGS)

AGS is the prototypic type I interferonopathy characterized by early-onset neurological disease mimicking an in utero viral infection. Following advancements in genetic sequencing, seven subtypes of AGS have now been recognized, each associated with a specific gene. The disease-associated genes are involved with the processing of endogenous nucleic acids (TREX1, RNASEH2 subunits, SAMHD1, ADAR1) or detection and sensing of exogenous nucleic acids (*IFIH1*) (Crow and Manel, 2015). The LoF mutations in nuclease activity that result in the accumulation of nucleic acid molecules, or GoF mutations in the sensing gene *IFIH1* lead to an excessive type I IFN signaling.

AGS is a heterogenous disorder with a wide range of clinical features. There is a phenotypical variation between different causative genes, and even among patients carrying mutations in the same gene (Rice et al., 2020). One-fifth of all cases has neurological involvement with spasticity, dystonia, seizures, microcephaly, and basal ganglia calcification. Seemingly spontaneous fevers, as well as chilblains, are also associated with AGS as is a lupus-like syndrome. Low-titer autoantibodies are commonly found in the sera of AGS patients (Crow et al., 2015). The role of type I IFN in the AGS pathogenesis is further supported by reports of successful use of treatment strategies that downregulate the IFN pathway (Briand et al., 2019).

STING-associated vasculopathy with onset in infancy (SAVI)

STING, which stands for Stimulator of Interferon Genes, is a protein involved in coupling sensing of exogenous DNA to the type I IFN response. STING is typically activated by binding of cyclic GMP-AMP (cGAMP), produced by cGAMP synthase (cGAS) after cGAS binds to DNA of microbial or host origin. Subsequently, after transmigration from the ER to the Golgi, STING causes activation of interferon regulatory factor 3 (IRF3), resulting in the expression of interferon-stimulated genes (ISGs) and the production of type I IFN (Li and Chen, 2018; Ablasser and Chen, 2019).

SAVI is caused by heterozygous GoF mutations in the *TMEM173* gene, which encodes STING, resulting in constitutive activation of the protein (Liu et al., 2014). Patients tend to present with severe interstitial lung disease, severe vascular inflammation and skin ulceration, and acral necrosis. It is assumed that these clinical features develop as a result of high levels of interferon activity, however, in animal models neither type I IFN or IRF3 are necessary to recapitulate some disease features, and functioning T cells were required for the development of lung inflammation (Luksch et al., 2019). Nevertheless, similarly to AGS, therapeutic strategies that specifically block type I INF signaling (JAK inhibitors) have been used to ameliorate symptoms in some patients with SAVI (Sanchez et al., 2018).

Diseases of dysregulated lipid metabolism

Mevalonate kinase deficiency (MKD)

Mevalonate kinase (MVK) is a ubiquitously expressed enzyme with a key role in the biosynthesis of cholesterol and isoprenoids. Patients with mevalonate kinase deficiency can present with variable phenotypes including, mevalonic aciduria (MA), hyper IgD syndrome (HIDS), and disseminated superficial actinic porokeratosis (DSAP) (Drenth et al., 1999; Houten et al., 1999; Zhang et al., 2012). Patients with nearly absent enzymatic activity manifest severe developmental disabilities and fevers, while biallelic hypomorphic variants cause HIDS (van der Burgh et al., 2013).

Patients with HIDS typically develop symptoms in infancy manifesting with episodes of high fever, abdominal/joint pain, diarrhea, erythematous rash, swollen lymph nodes, and the disease onset is often triggered by immunization. The most common

HIDS associated variants are Ile268Thr and Val377Ile, accounting for more than 50% of patients across multiple populations. DSAP has been reported in patients of Asian ancestry and is caused by a monoallelic germ-line pathogenic variant and a second somatic pathogenic variant present in keratinocytes (Kubo et al., 2019). Defect in MVK activity leads to a lack of isoprenoids that play a role in post-translational protein modifications by prenylation of proteins that regulate the activity of pyrin and NLRP3 inflammasomes (Akula et al., 2016; Park et al., 2016). Mutant MKD cells have excessive production of IL-1 β . The inflammatory phenotype in patients with HIDS is ameliorated with anti-IL-1 therapy, while patients with MA may require HSCT (De Benedetti et al., 2018; Neven et al., 2007; Arkwright et al., 2007).

LPIN2 deficiency

LPIN2 is an enzyme with phosphatidate phosphatase activity that plays a role in downregulation of proinflammatory signaling induced by saturated fatty acids. LPIN2 catalyzes the conversion of phosphatidic acid to diacylglycerol (DAG), which works as a secondary lipid messenger by activating protein kinases and RAS signaling pathways, among others (Donkor et al., 2007).

LPIN2 loss of function leads to Majeed Syndrome, a rare, recessively inherited disorder characterized by the triad of early-onset chronic recurrent multifocal osteomyelitis (CRMO), dyserythropoietic anemia, and neutrophilic skin lesions (Ferguson et al., 2005; Cox and Ferguson, 2018). All reported cases of Majeed syndrome are identified in consanguineous families of Middle Eastern or Indian ancestry. The affected patients carry homozygous mostly truncated mutations that lead to reduced protein expression. LPIN2 has been shown to regulate the activity of the NLRP3 inflammasome. IL-1 blockade results in a dramatic improvement in clinical and laboratory parameters of inflammation in Majeed syndrome, corroborating that a loss of LPIN2 activity leads to upregulation in the IL1 signaling pathway (Herlin et al., 2013).

PLC γ 2-associated diseases

Phospholipase C2 (PLC γ 2) enzyme is activated by B cell and Fc receptors to catalyzes the formation of secondary messengers, inositol triphosphate (IP $_3$) and DAG from phosphatidylinositol 4,5-bisphosphate (PIP2). Binding of released IP $_3$ to IP $_3$ receptors results in intracellular calcium release and activation of various signaling pathways including, MAP kinases (MAPK) (Gorjestani et al., 2011).

Heterozygous pathogenic mutations in *PLCG2* lead to two distinct phenotypes: PLC γ 2-associated antibody deficiency and immune dysregulation (PLAID) and autoinflammation, antibody deficiency, and immune dysregulation (APLAID). In both conditions, B cell immunodeficiency is the cause of recurrent bacterial respiratory and GI infections. PLAID patients present with early-onset symptoms of cold-induced urticarial or blistering rash, variable degrees of immunodeficiency and autoimmunity, and potentially tissue destructive skin granulomas (Ombrello et al., 2012; Milner, 2015). This phenotype is caused by in-frame genomic deletions spanning the cSH2 autoinhibitory domain of PLC γ 2, which results in a release of the protein active site. The mutant protein exhibits a reduction in PLC2-mediated activity at physiologic temperature and enhanced signaling at sub-physiologic temperatures. Mast cells are spontaneously activated when exposed to lower temperature.

APLAID is a rare severe disease manifesting early in life with fever, blistering or erythematous skin lesions, progressive interstitial lung disease, enterocolitis, ocular inflammation, and arthralgia (Zhou et al., 2012; Moran-Villasenor et al., 2019; Neves et al., 2018; Martín-Nalda et al., 2020). APLAID patients carry GoF missense mutations in the same cSH2 autoinhibitory domain of PLC γ 2, which cause increased release of intracellular Ca $^{2+}$ and upregulation of the NLRP3 inflammasome (Chae et al., 2015). PLAID and APLAID patients with immunodeficiency require immunoglobulin replacement therapy, while patients with severe inflammatory phenotype are treated with corticosteroids and cytokine inhibitors.

LACC1 deficiency

LACC1 encodes for the protein FAMIN (Fatty Acid Metabolism and Immunity Nexus), which promotes fatty acid oxidation and lipogenesis to ensure energy sources available for proper macrophage function (Cader et al., 2016).

Common missense variant, Ile254Val variant (rs3764147) in *LACC1* have been linked to leprosy and Crohn's disease (CD) by GWAS (Liu et al., 2015; Assadi et al., 2016; Wang et al., 2018). The novel pathogenic variant Cys284Arg is identified in children with recessively inherited early-onset CD and in children with systemic juvenile idiopathic arthritis (SoJIA) (Patel et al., 2014; Wakil et al., 2015). Patients diagnosed with SoJIA have the characteristic quotidian fevers, evanescent rash, and symmetrical polyarthritides like children with a typical polygenic SoJIA. Juvenile idiopathic arthritis has emerged as another *LACC1*-associated phenotype. All reported patients have been identified in consanguineous families from Saudi Arabia and other Middle Eastern countries (Karacan et al., 2018). Functional confirmation experiments of *LACC1* pathogenic variants demonstrated a decrease in protein expression, indicating that the disease is caused by loss of function of FAMIN. Effective treatment modalities include TNF blockade with adalimumab or IL-6 inhibition with tocilizumab (Kallinich et al., 2016).

Other monogenic autoinflammatory diseases

SH3BP2 deficiency/cherubism

The SH3-binding protein (SH3BP2) is an adaptor protein expressed in most cell types with a role in regulation of various signal transduction pathways. Dominantly inherited or de novo missense mutations in *SH3BP2* lead to activation of various inflammatory pathways and stimulate excessive osteoclastogenesis (Ueki et al., 2001). Activated tissue macrophages and osteoclasts give rise to disproportionate bone resorption. Cherubism occurs in children and is characterized by painless bone cyst-like lesions and excessive bone degradation of the upper and lower jaws. These lesions are then replaced with fibrous tissue masses, which cause a prominent swelling and deformities in the lower portion of the face. In some patients, the condition is associated with problems with teething, speech, and swallowing. The limitation of bone lesions to jaws is likely explained by the requirement for rapid bone remodeling during childhood in connection with secondary dentition. Enlargement of the jaw usually stabilizes during puberty, and some patients fully recover without the need for any intervention (Papadaki et al., 2012).

Coagulation factor XII (FXII)-associated autoinflammatory disease

Coagulation factor XII (FXII) is a plasma protein with thromboinflammatory properties and drives production of the inflammatory peptide bradykinin. Pathogenic variants in the *F12* gene, which encodes FXII, have been associated with potentially life-threatening hereditary angioedema (HAE). A specific missense mutation, Trp268Arg, which results in protein activation has been identified in a four-generation family with FCAS-like phenotype manifesting with cold-inducible generalized urticarial rash, fever, chill, headache, arthralgia, and fatigue (Scheffel et al., 2020). This variant causes changes in protein conformation and exposes the activation loop, which is otherwise buried in wild type protein. The mutant protein activates the kallikrein-kinin pathway and induces increases in IL-1 β secretion. Biopsies of lesional skin upon cold exposure revealed moderate dermal oedema, and perivascular infiltrates composed of macrophages. Neutrophils are identified as the source of FXII in the skin of patients. All patients reported complete unresponsiveness to oral antihistamines. Treatment with the bradykinin B2 receptor antagonist, icatibant, resolves symptoms of oedema and cold-induced inflammation.

Deficiency of adenosine deaminase type 2 (DADA2)

Adenosine deaminase (ADA) plays a role in purine metabolism by catalyzing the deamination of adenosine (Ado) and 2'-deoxyadenosine (dAdo) into inosine and deoxyinosine, respectively. ADA2 is a secreted protein produced by activated myeloid cells.

Deficiency of adenosine deaminase type 2 (DADA2) is a recessively inherited disease associated with hypomorphic or LoF mutations that result in low or absent ADA2 activity (Zhou et al., 2014; Navon Elkan et al., 2014). Diagnosis is established either by genetic testing or by measuring plasma or serum ADA2 activity. DADA2 is a type of medium-size vessel vasculitis with histologic findings consistent with polyarteritis nodosa (PAN) (Meyts and Aksentjevich, 2018). Livedoid rash is the most common skin manifestation; subcutaneous nodules, Raynaud's, warts, ulcerations, and distal vascular occlusion are other skin features. Neurological impairments are the consequence of lacunar ischemic infarcts in the deep-brain nuclei, midbrain, and/or brainstem, in addition, hemorrhagic strokes have been observed in a subset of patients. Hematological manifestations, including aplastic anemia, pure red cell aplasia, lymphopenia, neutropenia, and thrombocytopenia, have been reported in patients with absent ADA2 activity. A subset of patients was diagnosed with CVID or autoimmune manifestations resembling systemic lupus. Hypogammaglobulinemia, in particular low IgM levels, in children presenting with fevers indicates DADA2 in the differential diagnosis. Deficiency of ADA2 causes an imbalance in the differentiation of macrophages with a paucity of anti-inflammatory M2 macrophages and activation of neutrophils (Carmona-Rivera et al., 2019). Elevated levels of the proinflammatory cytokines TNF and IL-1 have been identified in skin biopsies and blood samples of DADA2 patients. Primary treatment of DADA2 relies on anti-TNF agents in patients with an inflammatory phenotype, while patients with bone marrow failure may require HSCT (Hashem et al., 2017, 2021; Ombrello et al., 2019).

Conclusion

The family of autoinflammatory disorders has grown rapidly to incorporate many novel biological mechanisms involved in the inflammatory processes. Various attempts have been made to classify SAIDs. However, irrespective of the approach used, be it according to the genetic cause, predominant clinical features, the principal biological pathway, or response to treatment, there have always been exceptions. For example, FMF and PAAND are both caused by the GoF mutations in *MEFV*, but the clinical features and response to therapy of these two disorders vary considerably. Similarly, HA20, which is classified as a disorder of dysregulated ubiquitination, might also have interferonopathy-like features, since it seems that type I IFN signature predicts a positive response to JAKi in some patients.

Nevertheless, some way of classifying these disorders is necessary, if nothing else, to provide a framework to deal with new discoveries in the field. However, an alternative approach to patients who present with clinical features suggestive of SAID, might be

to perform, rapid, unbiased, genotyping, combined with detailed cytokine profiling and immunological characterization, to fully appreciate all factors involved in the disease pathogenesis. Such an approach, which has recently been described, might help to inform treatment choices even in the cases where the genetic basis of the disease is unknown (De Jesus et al., 2020) and bring forward the concept of personalized medicine closer to reality. For selective patients with unusually severe phenotypes of systemic inflammation and/or features of combined immunodeficiency, severe immune dysregulation or bone marrow failure, as well as those unresponsive to conventional and/or biologic therapies, allogeneic HSCT is a valid treatment possibility (Greco et al., 2019; Chan et al., 2020; Abinun and Slatter, 2021). Cautious patient selection is mandatory, as well as performing HSCT in experienced transplant centers with multidisciplinary team involvement.

Introduction

The knowledge about inborn errors of immunity (IEI), also named as primary immunodeficiencies has increased very fast in the last years. The access to genetic defects improved our comprehension about the variability of phenotypes related to molecular findings (Tangye et al., 2020). Complement deficiencies are usually hereditary. The most common type is autosomal recessive form, including C1, C2, C3, C4, C5, C6, C7, C8, C9, and Mannan-binding lectin deficiencies (Schröder-Braunstein and Kirschfink, 2019). A X-linked recessive pattern has been described for properdin deficiency. Probably more often, complement deficiencies are acquired through complement overconsumption, protein synthesis dysfunction, protein loss disorders, autoimmunity, and high catabolic states. Findings such as complement defects underlying atypical hemolytic uremic syndrome (aHUS) or in the lectin pathway are subject to diverse interpretations (Hirt-Minkowski et al., 2010; Michalski et al., 2015).

The actual prevalence of complement deficiencies is still unknown. Most estimations have been based on selected populations such as tertiary hospitals, or single-center registries. National registries show a wide variability in the frequencies of these defects, comprising between 1% and up to 30% of all primary immunodeficiencies (Abolhassani et al., 2018, 2020; Mukhina et al., 2020). According to the European Society for Immunodeficiencies (ESID) registry, deficiencies of complement proteins were responsible for approximately 5% of all primary immunodeficiencies (PID) between 2004 and 2020 (<http://esid.org/Working-Parties/Registry/ESID-Database-Statistics>; <https://cci-reporting.uniklinik-freiburg.de/#/>).

There are several aspects influencing the diagnosis of complement defects. The awareness about clinical symptoms is still restricted (Grumach and Kirschfink, 2014). Nowadays, the best example is the hereditary angioedema (HAE) with a high investment in the diagnosis, reflected by a more frequent identification of patients. Some casuistries of complement deficiencies showed half of the patients being diagnosed with hereditary angioedema (Mukhina et al., 2020; Genel et al., 2018). However, the estimated prevalence for HAE with C1 inhibitor deficiency is 1:50,000 and it is less common than MBL, C2, C5-C9 deficiencies (Mukhina et al., 2020). The analysis of complement-deficient patients included in ESID registry ($n = 77$) excluding HAE patients (Turley et al., 2015), revealed that 43% had defects in the classical pathway (CP), 31% in the alternative pathway (AP), and 26% defects of terminal complement components. C2 deficiency was the most common of the observed deficiencies (29% of the total) (Turley et al., 2015). Partial deficiencies, such as of C4, may be of relevance in certain clinical situations (Grumach et al., 2006).

Complement plays an essential role in both innate and adaptive immune responses. In cooperation with other immune and physiological systems, complement mediates the clearance of immune complexes, cellular debris and apoptotic cells, contributes to normal tissue and organ development, and promotes tissue repair after injury (Hajishengallis et al., 2017). A dysfunction in this system in terms of upregulation, downregulation, or dysregulation can cause a wide range of effects, including disturbance of normal host defense and altered inflammatory response (Botto et al., 2009).

Clinical history is the most important initial diagnostic tool for ruling out a complement deficiency. Severe or multiple infections, caused by capsulated bacteria as *Streptococcus*, *Haemophilus* and *Neisseriae* or autoimmune diseases in particular with childhood onset are the main clinical manifestations associated with complement deficiency (Brodzski et al., 2020). In a recent

study with more than 200 patients, infections corresponded to approximately 70% of the clinical picture, mostly caused by *Meningococcus* or *Pneumococcus*. Autoimmune disorders occurred in 14% of the cases. In addition, kidney disease (aHUS) or C3 Glomerulopathy, C3G) was also reported (El Sissy et al., 2019). The milder symptomatology related to some complement defects in comparison with other Inborn Errors of Immunity could justify the reduced identification of affected patients; nevertheless, the most relevant point to be emphasized is the difficulty to access specific assays and manipulate the samples for complement diagnosis. The thermolability and the involvement of complement proteins as acute phase reactants often leads to misdiagnosis. In addition, there are only few laboratories developing laboratorial and molecular diagnosis for primary complement deficiencies (Prohászka et al., 2018; Grumach and Kirschfink, 2014; Costa-Carvalho et al., 2017).

Complement system

The complement system forms an elaborate network of fluid-phase, cell surface-associated, and intracellular proteins, which either function as pattern-recognition molecules, proteases/convertases, regulators, or signaling receptors, collectively mediating immune surveillance and tissue homeostasis (Ricklin et al., 2010).

There are three major complement activation pathways (Fig. 1): the classical pathway (CP) initiated via antigen-antibody complexes, the alternative pathway (AP) through any permissive surface and the lectin pathway (LP) by the interaction of pattern-recognition mannose-binding lectins (MBL) or ficolins with carbohydrate ligands on the surface of the pathogens.

Fig. 1 Complement activation pathways and assembly of the terminal pathway. The classical pathway is initiated by the binding of the C1 complex to antibody already bound to antigen, leading to the formation of the C4b2a enzyme complex (C3 convertase). The lectin pathway is activated by the binding of either MBL or ficolin and MASP 1, 2 and 3, respectively, to an array of mannose groups on the surface of bacterial cells and the generation of C3 convertase of the classical pathway. The alternative pathway is initiated by hydrolyzed C3 and factor B and the subsequent formation of the alternative pathway C3-convertase, C3bBb. Generation of the C3-convertase allows the formation of the C5 convertase, which initiates the formation of the C5b-9 terminal complement complex. The complement system is regulated at several levels: CD55, CR1, CD46, C4bp, and factors I and H regulate the activity of the C3-convertase and C5-convertase, and CD59 blocks the final assembly of MAC by preventing the binding of C9. S protein/vitronectin binds to C5b-7 and leads to the formation of a cytolytically inactive sC5b-9 complex.

The convergence point of complement activation pathways is the formation of the C3 convertase which cleaves the C3 molecules into C3a (one of two major anaphylatoxin molecules) and C3b, which is a potent opsonin. C3b and its degradation products iC3b and C3d bind to intact target cells or cell debris and act as ligands for complement receptors CR1 (CD35), CR3 (CD11b + CD18), and CR2 (CD21), respectively, expressed by myelomonocytic cells, lymphocytes and follicular dendritic cells. The binding of C3b or its metabolites to the correspondent cell receptors is crucial for cell to cell interaction of the innate and adaptive immune responses and for removing apoptotic and necrotic cells (Ricklin et al., 2010). Consecutive activation and binding of C3 leads to the generation of the C5 convertase complex which cleaves C5 into C5a and C5b. The anaphylatoxin C5a recruits neutrophils to the areas of inflammation and exerts tissue damage. The membrane attack complex (MAC or C5b-9) is formed by generating a complex between C5b, C6, C7, C8 and multiple C9 which inserts into the cell membrane of target cells. MAC formation disrupts the phospholipid bilayer of the cell membrane, which causes massive calcium influx, loss of mitochondrial membrane potential and cell lysis (Hajishengallis et al., 2017). Collectively, the main three consequences of complement activation are (1) tagging target cells by C3b-metabolites for phagocytosis, (2) recruitment of inflammatory cells by C3a and C5a, and (3) MAC-mediated cell lysis (Fig. 1).

Complement deficiencies

Deficiencies of the classical pathway

Patients deficient in the initial components of the classical pathway are prone to autoimmune connective tissue diseases, such as SLE, and other autoimmune diseases, e.g., dermatomyositis, Henoch-Schönlein purpura, juvenile rheumatoid arthritis and glomerulonephritis (Macedo and Isaac, 2016). Out of all cases of SLE only a small fraction is associated with complement deficiency, indicating that SLE is a highly multifactorial disease (Degn et al., 2011). Genetic factors influencing the predisposition to SLE was verified evaluating monozygotic and dizygotic twins (Deapen et al., 1992), however environmental factors are also involved (Macedo and Isaac, 2016). Deficiency of the early components of the complement system classical pathway (CP), mainly C1q (90–93%), C1r/C1s (50–57%), C4 (75%), and C2 (10%) represent clearly a genetic susceptibility to SLE.

C4 deficiency is also extremely rare. This could be due to variations in C4 gene copy number with two to seven copies found in the diploid genome. Multiple mutations have to occur for deficiency to result (Degn et al., 2011). Individuals with heterozygous C2 or C4 deficiency often remain asymptomatic (Macedo and Isaac, 2016).

Deficiency of C2 is, on the other hand, generally associated with a slight increase in the prevalence of autoimmune disease. Furthermore, about half of the patients identified with C2 deficiency had a history of invasive infection with encapsulated bacteria. Family members lacking C2 but not showing clinical symptoms were often encountered (Degn et al., 2011).

Although the occurrence of autoimmunity and autoantibodies have been highlighted, patients with CP defects also develop an increased susceptibility to infections. It is estimated that ~50% of patients develop severe bacterial infections including meningitis, pneumonia, arthritis, or septicemia. These infections are caused by encapsulated bacteria, most commonly *Streptococcus pneumoniae*. Infections and vascular diseases represent the leading causes of death in these patients (Brodzski et al., 2020).

Deficiencies of the alternative pathway

Defects in proteins of the classical and terminal pathways are more frequent than those of components of the alternative pathway (properdin, factor D, and factor B) which account for only 2.5% of all complement deficiencies (Audemard-Verger et al., 2016). Properdin deficiency is the only complement protein inherited in a X-linked pattern and is often associated with fulminant meningococcal disease (López-Lera et al., 2019). It manifests with either complete absence of the molecule (type I), partial deficiency (type II) or a normal level of dysfunctional protein (type III). Properdin-deficient individuals are susceptible to meningococcal disease, which is frequently complicated by sepsis and most commonly occurs in adolescence (Brodzski et al., 2020). The risk of meningococcal infection in healthy individuals is usually greatest in children aged less than 2 years, when protective antibodies against meningococcal serotypes have not developed. In patients with properdin deficiency, the median age at the time of meningococcal infection is much higher at approximately 14 years of age (Overturf, 2003). Factor D deficiency was reported in less than 10 cases and it is also considered as a predisposing factor for meningococcal infection. Factor B deficiency has been described only twice and both patients presented recurrent bacterial infections caused by encapsulated bacteria. It is important to mention that the investigation of these proteins is scarce (Slade et al., 2013; Gauthier et al., 2020). Factor B variants were identified only rarely as the genetic cause in cases of aHUS (Brodzski et al., 2020).

C3 deficiency

C3 plays a central role in all three activation pathways and it is not surprising that its deficiency has been associated with severe recurrent pyogenic bacterial infections and immune complex-mediated diseases (Reis et al., 2006). The infections develop early in life and have a tendency to recur (da Silva et al., 2016). They are mainly caused by gram-negative bacteria, such as *Neisseria meningitidis*, *Enterobacter aerogenes*, *Haemophilus influenzae* and *Escherichia coli*. In addition, besides *Streptococcus pneumoniae*, infections caused by other gram-positive organisms, including *Streptococcus pyogenes* and *Staphylococcus aureus*, have also been observed in C3-deficient patients. The infections affect the upper and lower respiratory tract including pneumonia, episodes of sinusitis,

tonsillitis and otitis. Severe infectious complications also occur, e.g., pneumonia, meningitis, osteomyelitis, or bacteremia meningitis. Patients may also experience membranous glomerulonephritis, while symptoms consistent with SLE are less frequent. Rare C3 gain of function (GoF) mutations may lead to aHUS (Brodzski et al., 2020). One common and several rare variants in C3 have been associated with an increased risk of age-related macular degeneration (AMD) (Schramm et al., 2014).

Lectin pathway

Lectin pathway impairment due to insufficient production of any of these components is common and may be associated with several phenotypes as increased risk of infection, especially in young children and otherwise immunocompromised individuals. An association to autoimmunity has also been reported (Heitzeneder et al., 2012). In addition, there are studies showing the influence of lectin pathway on the severity of diseases (Jensenius et al., 2003; Brodzski et al., 2020). As mentioned before, polymorphisms in complement genes are linked to, for example, atypical hemolytic uremia and age-dependent macular degeneration. Polymorphisms in the collectin and ficolin genes cause variable degrees of insufficiency and no measurable ficolin 3 was associated with recurrent infections diseases in a 32-year-old man (Hummelshoj et al., 2005; Munthe-Fog et al., 2009).

The clinical impact of low MBL levels has attracted considerable interest in 'MBL deficiency'. MBL deficiency is still being used to classify some state of immunodeficiency, however, the definition of what constitutes MBL deficiency is unclear (Heitzeneder et al., 2012). MBL deficiency was identified in 5% of European descent, considering plasma levels below 100 ng/ml. A higher frequency was described for Sub-Saharan Africans (Degen et al., 2011). MBL insufficiency is, in combination with other factors, associated with more severe forms of sepsis and fatal outcomes, irrespective of the causal microorganisms (Brodzski et al., 2020).

MBL is a pattern recognition molecule involved in opsonization as well as in complement activation. Therefore, it seems evident that low MBL levels could be disadvantageous in circumstances in which the integrity of innate immunity is essential for protection against infections, e.g., in infancy. On the other hand, low MBL levels may be advantageous if strong complement activation is linked to extensive tissue damage. This notion implies that the impact of a given MBL status is context-dependent (Heitzeneder et al., 2012).

MBL deficiency was related to upper respiratory infections in children and it was reported a higher risk for severe meningococcal or pneumococcal infections at this age (Grumach and Sullivan, 2019). A controversial role of MBL deficiency has been described in severe infections, septicemia, or affecting the severity in certain diseases. Also, patients with HIV infection, under chemotherapy and after stem cell transplantation appear to be more susceptible to severe infections if MBL deficiency is associated (Heitzeneder et al., 2012). On the other side, the MBL deficiency could be beneficial in certain infections caused by *Leishmania* or *Mycobacteria* (de Messias-Reason et al., 2007). MBL levels could also influence the susceptibility and severity of autoimmune disease, reported for inflammatory bowel disease and systemic lupus erythematosus (Vignesh et al., 2017). Thus, the MBL status appears as a modifier, either aggravating the severity or improving the course of a disease according to its polymorphism.

Mannose-associated serine protease 1 (MASP1), the most abundant protease of the lectin pathway, has a central role in pathway activation via MASP2. 3MC syndrome is characterized by facial dysmorphism and other developmental defects such as cleft lip and palate, postnatal growth deficiency, cognitive impairment, and hearing loss. It is caused by homozygous mutations in the MASP1 gene (3MC syndrome 1) or members of the collectin subfamily COLEC10 or COLEC11 (3MC syndrome 2). Excess or unusual infections and autoimmunity have not yet been described in this syndrome (Brodzski et al., 2020).

A case of MASP-2 deficiency was originally described in a patient with persistent inflammatory disease, episodes of severe pneumococcal pneumonia and progressive lung fibrosis (Stengaard-Pedersen et al., 2003). Additional studies revealed that only a low clinical penetrance of MASP-2 deficiency is seen (Beltrame et al., 2015).

Ficolin-3 deficient cases manifest variable clinical symptoms, particularly infections, autoimmune disorders and neurological complications. Only a few homozygous cases have been described and different clinical symptoms including enterocolitis, respiratory and skin infections, brain abscess, refractory seizures and nephrotic syndrome have been observed (Babaha et al., 2020).

Deficiency of terminal components

Defects of terminal complement components (C5 through C9) are almost exclusively associated with an increased risk for recurrent invasive meningococcal disease and disseminated gonococcal infection (Figueroa and Densen, 1991). C9 deficiency, which is extremely rare in Caucasians, was detected in about 0.1% of Japanese blood donors, however without clinical consequences (Figueroa and Densen, 1991; Grumach and Kirschfink, 2014). Although meningococcal infection may occur at all ages, there is a peak incidence in children aged <2 years, which can be explained by the absence of specific protective antibodies (Grumach and Kirschfink, 2014). The average age of onset of symptoms in patients with terminal pathway deficiencies is 17 years. In children above 5 years of age with meningococcal meningitis there is a higher probability for a complement deficiency. Uncommon serogroups, W-135, X, Y, or Z, are more frequently related to a terminal complement component deficiency (Grumach and Kirschfink, 2014). Recurrence of diseases is another characteristic feature; almost 50% of individuals with deficiencies in components of the terminal pathway will experience at least one additional episode (Lewis and Ram, 2020). Access to specific immunization may change this profile (Ram et al., 2010). Persons with inherited terminal component deficiency experience a lower mortality per meningococcal episode compared to complement-sufficient patients (1.5% versus 19% mortality per 100 episodes). Mortality and severity of meningococcal disease is proportional to the degree of complement activation and endotoxin levels in plasma (Lewis and Ram, 2020).

Deficiencies of complement regulation

The powerful activation cascades of complement system require tight regulation to maintain appropriate homeostasis and to avoid excessive damage to self. An impaired function of these regulatory proteins is often deleterious (Liszewski and Atkinson, 2015). A broad clinical phenotype is associated with the impairment of this control system. A number of genetic alterations are associated with increased risk of developing inflammatory renal (aHUS, C3G) and ophthalmic disorders (AMD). The spectrum of clinical presentations also includes angioedema (C1 inhibitor [C1-INH] deficiency), protein-losing enteropathy (CD55 deficiency), and paroxysmal nocturnal hemoglobinuria (PNH) (CD55 + CD59 deficiency) (Noris and Remuzzi, 2009; Liszewski and Atkinson, 2015; Brodzski et al., 2020). It is important to note that, in contrast to complete deficiencies of complement regulatory proteins that result in consumption of multiple components in a pathway, haploinsufficiency can cause excessive local inflammation occurring at sites of tissue injury or debris accumulation, potentially initiated by endothelial cell damage. For example, haploinsufficiency of FH predisposes to aHUS and AMD, while homozygous FH deficiency results in alternative pathway activation, cleavage and consumption of C3 and FB, leading to increased susceptibility to pyogenic infections. Heterozygous deficiency of FI is also associated with both aHUS and AMD. PNH results from mutations in the glycosylphosphatidylinositol anchor affecting the two membrane-bound inhibitors of the complement system, decay-accelerating factor (DAF, CD55) and membrane inhibitor of reactive lysis (MIRL, CD59) (Degen et al., 2011). The complement system attacks the erythrocytes lacking these control proteins, causing PNH. Guillain-Barré-like neurological symptoms with hemolysis are the hallmark of rare cases of isolated CD59 deficiency.

Hereditary angioedema (HAE) caused by deficiency of C1-INH is inherited in an autosomal dominant trait. Besides controlling complement system activation, of C1 inhibitor regulates the fibrinolytic, coagulation and contact systems. Lack of inhibition results in excessive bradykinin generation, which in turn increases vascular permeability, leading to angioedema. The onset of the disease is early in life, causing subcutaneous and submucosa edema. The symptoms are edema affecting the face, periphery, genitals, abdomen and larynx. The upper airway obstruction can result in asphyxia if not treated. An acquired form of C1 inhibitor deficiency mostly occurs above the 4th decade of life and is associated with lymphoproliferative disorders and the presence of autoantibodies to C1 inhibitor. Another type of HAE was identified in patients with normal C1-INH levels. Mutations in genes coding for factor XII (FXII-HAE), plasminogen (PLG-HAE) and, in few families, angiopoietin-1, kininogen-1 or myoferlin have been found in this newly-defined group of primary angioedema patients. In a significant proportion of HAE patients with normal C1 inhibitor, mutations have not been detected yet (Bork et al., 2020).

Factor H and Factor I are regulators of the AP causing secondary C3 deficiency. Recurrent infections are expected in the deficiency of any of these factors (Leitão et al., 1997; Falcão et al., 2008). Approximately 50% of patients with aHUS have genetic mutations of FH, FI, C3, FB and/or MCP, and deletion of complement FH-related proteins 1 and 3 (CFHR1/CFHR3) (Nester et al., 2015). Mutations in FH, MCP and FI have also been reported in C3 glomerulopathy (formerly known as membranoproliferative glomerulonephritis (MPGN)), as well as those presenting with pre-eclampsia and hemolysis, elevated liver enzyme levels, and low platelet levels (HELLP) syndrome. Partial FI deficiency has also been previously associated with clinical manifestations including recurrent tonsillitis, urinary infections, otitis, pyelonephritis, severe meningitis and sepsis (Grumach et al., 2006).

Dysregulation of the AP appears to also play a significant role in the pathogenesis of age-related macular degeneration (AMD), which is the most common cause of vision loss in developed countries. Polymorphisms in genes encoding for FH, C3 and FI, have been associated with AMD (Brodzski et al., 2020).

Laboratory diagnosis of complement deficiencies

The work-up of complement deficiencies requires the combined laboratory analysis of multiple aspects of the complement system such as the functionality and the activation state of the different pathways, the concentration and function of single component and regulators, the presence of auto-antibodies as well as the molecular analysis of complement related genes (for reviews see: Prohaszka et al., 2018; Ekdahl et al., 2018; Schröder-Braunstein and Kirschfink, 2019; Gavrilaki and Brodzki, 2020).

When complement deficiency is considered as a differential diagnosis, in a first step, a set of tests assessing the functionality of the classical and the alternative pathway (CH50 and AH50) as well as the activation state of the complement system should be performed ("complement status"). If indicated clinically, the integrity of the lectin pathway should also be investigated. The combined results of these assays allow to determine whether a loss of pathway functionality is due to a primary (inherited) defect of complement factors or mostly likely caused by consumption of complement factors following strong complement activation (secondary defect). Furthermore, they allow to distinguish between defects affecting pathway-specific components (C1/ C2/C4 vs. FB /FB/Properdin vs. MBL/MASP1/2) and impairment the common terminal pathway (C3-C9).

In case the results of these assays suggest a primary complement defect, the analysis of individual complement components (including regulators) is indicated. The latter includes the determination of the concentration of single factors as well as functional test such as resubstitution and titration assays. Furthermore, flow cytometric analysis is employed to examine expression levels of complement regulators, such as CD55 or CD59 on cell membranes. Finally, genetic analysis will provide insight into gene variants underlying suspected inherited complement defects (Liszewski et al., 2017).

Importantly, the laboratory analysis of complement deficiencies also involves the analysis of inhibitory or activating autoantibodies targeting individual complement components including regulators (e.g. anti-C1q, anti-FH, C3 nephritic factor). By interfering with the function of the respective components, these autoantibodies represent clinically relevant causes of secondary complement deficiencies (Ekdahl et al., 2018).

Preanalytics

Conclusive complement analysis critically depends on correct sampling and subsequent preanalytical handling of the samples. Whereas serum is required for functional analysis of the complement pathways and suitable for measuring the concentration of complement components as well as autoantibodies, the quantification of activation products needs to be performed using EDTA plasma. By chelating divalent cations such as Ca^{2+} and Mg^{2+} , EDTA at concentrations of 10 mM or higher inhibits convertase activity and thereby prevents complement activation as occurring rapidly *ex vivo*. Importantly, as another measure to prevent *ex vivo* complement activation, serum and EDTA plasma have to be separated from whole blood samples as rapidly as possible. Subsequently, they need to be subject to immediate analysis (e.g. within 4 h if stored on ice or at 4 °C) or to be frozen at -80 °C until being assayed or shipped to specialized laboratories on dry ice (Mollnes et al., 1988).

For more details, the reader is referred to the detailed description of a comprehensive complement analysis in this encyclopedia.

Treatment of complement deficiencies

General considerations

Treatment of complement deficiencies includes antibiotic prophylaxis, immunization covering encapsulated bacteria, pneumococcal, *Haemophilus* and meningococcal [types A, C, W, Y, and B] vaccines, and prompt workup for sepsis if the clinical symptoms suggest bacterial infection (Ochs and Petroni, 2018). Autoimmune diseases are treated symptomatically, using the same immunosuppressive agents and anti-inflammatory medications as those used in the general population. Management of hereditary angioedema has been revolutionized by C1-esterase inhibitor concentrate, and by kallikrein inhibitor or bradykinin receptor antagonist preparations (Betschel et al., 2020).

Vaccination

There is no contra indication to use routine vaccination for complement deficient patients. Considering the susceptibility to encapsulated bacteria, it is important to indicate vaccines against pneumococcus, *Haemophilus influenzae*, and *Neisseria meningitidis*. Conjugated vaccines can be applied early in life and they represent the best choice (Ram et al., 2010). Children less than 2 years do not respond to nonconjugated vaccine. A two-dose of meningococcal conjugate vaccine has been recommended for patients with complement deficiencies and asplenia and it is important to check vaccine response in order to offer protection against bacterial infections (Brady et al., 2011). House contacts should also receive the same vaccines in order to reduce the possibility of transmission. For patients with HAE who may require blood products as part of their therapy, hepatitis B vaccination is recommended (Betschel et al., 2020).

Antibiotics

The use of antibiotic prophylaxis in complement deficiencies is aimed at protecting against infection by encapsulated organisms and it is best reserved for patients exhibiting recurrent infections despite appropriate vaccination (Bonilla et al., 2005; Brodzski et al., 2020). Monthly benzathine penicillin was described to be protective against *Neisseria* infection in 40 patients with homozygous C6 deficiency (Potter et al., 1990). This study was performed before general application of meningococcus vaccines. Other protocols evaluated the use of amoxicillin prophylaxis in children with recurrent acute otitis media where reduction of the infections was more evident in the first 6 months of treatment in comparison with placebo (Roark and Berman, 1997). In contrast, antimicrobial prophylaxis wasn't advised by others (Teele et al., 2000).

Specific therapies

Specific complement targeted therapies has developed enormously in this century. aHUS and PNH is now properly controlled with Eculizumab, a humanized monoclonal antibody that binds to C5, which prevents its cleavage C5a and C5b, thereby inhibiting the generation of the terminal complement complex C5b-9 (Mache et al., 2009). Hemolysis may still occur in some patients with PNH despite treatment with eculizumab, most probably due to unrestricted extravascular hemolysis. More recently, Ravulizumab, a long-acting, second-generation C5 inhibitor, was approved, to be administered intravenously every 8 weeks, with good comparable results to Eculizumab (Kulasekararaj et al., 2019). More complement inhibitors are now in phase 2 and phase 3 clinical studies potentially allowing a better disease-tailored complement intervention (Mastellos et al., 2019).

The treatment of Hereditary Angioedema progressed in the last years with the inclusion of new drugs for prophylaxis. Besides the use of intravenous plasma derived C1 inhibitor in several countries, the recombinant C1 inhibitor and the formulation for subcutaneous use of C1 inhibitor were available. More recently, the therapy focusing kallikrein has been developed with the launching of Lanadelumab (subcutaneous use) and Berotralstat (oral use). Regarding the attacks of angioedema, Icatibant, an inhibitor of bradykinin receptor, and Ecallantide, a kallikrein inhibitor, in addition to the intravenous C1 inhibitor, have been available decreasing the risk of death due to asphyxia (Cicardi et al., 2014; Betschel et al., 2020). Several drugs acting in the contact system have been under clinical trials (phases I and II) in patients with Hereditary Angioedema. In addition, the expansion of the indications for HAE with normal C1 inhibitor and children will be accessible soon (Fijen et al., 2021).

Conclusions

Complement deficiencies mainly manifest by recurrent infections caused by encapsulated bacteria, autoimmunity, recurrent angioedema without wheals and inflammatory disorders involving kidney and eyes. Family history of consanguinity directs to an autosomal recessive inheritance, described for most of the components excepts for Properdin (X-linked) and C1 inhibitor (autosomal dominant) deficiencies. Due to the limited access to laboratorial diagnosis, we can suppose that complement deficiencies are underdiagnosed. The progress on therapies for complement deficiencies and its manipulation have opened new perspectives for the patients. A better approach to the patients will certainly establish the need for adequate laboratorial diagnosis.

Introduction

The study of immune deficiencies is mainly focused on inborn errors of immunity. Yet, it is not that uncommon for a patient to have a presentation resembling that of a well-known primary immunodeficiency (PID) yet presenting at an older age or without any demonstrable genetic etiology. Two groups of phenocopies can lead to diseases with a clinical picture compatible with a heritable immunodeficiency (Table 1). Both somatic mutations and disease related to autoantibodies affecting the same pathway implicated in the inborn error can cause disease that resembles a heritable immunodeficiency. It is critical to recognize these diagnostic possibilities. Only a small number of scenarios have been identified, yet it is likely that they occur much more often. The recognition of patients with disease caused by a somatic mutation in a gene known to be critical for immune function is limited by technology and analytic approaches unless that pathologic cells are isolated and identification of patients with autoantibodies is limited by the lack of testing. Therefore, the diagnosis suggested by a strong clinical suspicion requires partnering with a laboratory experienced in the field.

Diseases associated with autoantibodies

AutoAb to IL-17A, IL-17F and/or IL-22/chronic mucocutaneous candidiasis

Chronic mucocutaneous candidiasis (CMC) is characterized by recurrent or persistent symptomatic mucocutaneous fungal infections affecting the nails, skin, and oral and genital mucosae. The lesions are usually caused by the commensal *Candida albicans*. Patients with severe combined immunodeficiency (SCID) and combined immunodeficiencies (CIDs), are also prone to CMC. However, in these PIDs associated with severe T cell defect, patients are also susceptible to many other infections. By contrast, in patients with autosomal dominant hyper IgE syndrome (AD-HIES) bearing dominant negative mutations of the *STAT3* gene, and in patients with autosomal recessive autoimmune polyendocrinopathy syndrome type I (APECED or AR APS-I) due to *AIRE* mutations, CMC is the principal or only infectious disease frequently observed (Puel et al., 2012). CMC has also been reported in one family with *CARD9* deficiency (Glocker et al., 2009). Patients with syndromic CMC have very small proportions of IL-17- and IL-22-secreting T cells. In a series of 33 APECED patients, anti-IL17 autoantibodies were identified in all of them, 29 of whom had CMC. They confirmed function of the anti-IL-17A antibody by inhibiting IL-6 production from IL-17 responsive fibroblasts (Puel et al., 2010). In another report on 162 APECED patients, anti-IL-17 A, IL-17F, and IL-22 autoantibodies were found in up to 90% of cases, also strongly associated with CMC (Kisand et al., 2010). High levels of neutralizing autoantibodies against IL-17A, IL-17F and/or IL-22 were documented in patients with APS-I presenting with CMC as their only infectious disease (Puel et al., 2012). These autoantibodies may precede onset of other features of APS-I (Wolff et al., 2013).

Some patients present with “isolated” CMC or CMC disease (CMCD), a clinical entity that usually begins early in infancy and affects otherwise healthy individuals. The molecular study of these patients led to the identification of the first three genetic aetiologies of CMCD: AR IL-17RA and AD IL-17F deficiencies and AD *STAT1* gain-of-function, impairing IL-17-producing T cell development. These data provided formal proof that IL-17 cytokines are crucial for mucocutaneous protection against *C. albicans*. However, no genetic etiology has yet been identified for a number of patients with CMCD. In addition, autoantibodies against IL-22 have been detected in patients with an APS-1 phenotype in the absence of a genetic diagnosis (Eriksson et al., 2018).

Table 1 Phenocopies of inborn errors of immunity.

	<i>Genetic defect/ presumed pathogenesis</i>	<i>Circulating T cells</i>	<i>Circulating B cells</i>	<i>Serum Ig</i>	<i>Associated features/similar PID</i>
<i>Diseases associated with autoantibodies</i>					
Chronic mucocutaneous candidiasis	AutoAb to IL-17 and/or IL-22	Normal	Normal	Normal	Chronic mucocutaneous candidiasis/CMC
Adult-onset immunodeficiency with susceptibility to mycobacteria	AutoAb to IFN γ	Decreased naive T cells	Normal	Normal	Mycobacterial, fungal, <i>Salmonella</i> , VZV infections/MSMD, or CID
Recurrent skin infection	AutoAb to IL-6	Normal	Normal	Normal	Staphylococcal infections/STAT3 deficiency
Pulmonary alveolar proteinosis	AutoAb to GM-CSF	Normal	Normal	Normal	Pulmonary alveolar proteinosis, cryptococcal meningitis, disseminated nocardiosis/CSF2RA deficiency
Acquired angioedema	AutoAb to C1 inhibitor	Normal	Normal	Normal	Angioedema/C1 INH deficiency (hereditary angioedema)
Thymoma with hypogammaglobulinemia (Good syndrome)	AutoAb to various cytokines	Increased CD8 + T cells	No B cells	Decreased	Invasive bacterial, viral or opportunistic infections, autoimmunity, PRCA, lichen planus, cytopenia, colitis, chronic diarrhea
<i>Diseases associated with somatic mutations</i>					
Autoimmune lymphoproliferative syndrome (ALPS–SFAS)	Somatic mutation in <i>TNFRSF6</i>	Increased CD4 – CD8 – double negative (DN) alpha/beta T cells	Normal, but increased number of CD5 + B cells	Normal or increased	Splenomegaly, lymphadenopathy, autoimmune cytopenias, Defective lymphocyte apoptosis
RAS-associated autoimmune leukoproliferative disease (RALD)	Somatic mutation in <i>KRAS</i> (GOF)	Normal	B cell lymphocytosis	Normal or increased	Splenomegaly, lymphadenopathy, autoimmune cytopenias, granulocytosis, monocytosis
RAS-associated autoimmune leukoproliferative disease (RALD)	Somatic mutation in <i>NRAS</i> (GOF)	Increased CD4–CD8–double negative (DN) alpha/beta T cells	Lymphocytosis	Normal or increased	Splenomegaly, lymphadenopathy, autoantibodies
RAS-associated autoimmune leukoproliferative disease (RALD)	Somatic mutation in <i>NRAS</i> (GOF)	Increased CD4 – CD8 – double negative (DN) alpha/beta T cells	Lymphocytosis	Normal or increased	Splenomegaly, lymphadenopathy, autoantibodies
Cryopyrinopathy, (Muckle-Wells/CINCA/NOMID-like syndrome)	Somatic mutation in <i>NLRP3</i>	Normal	Normal	Normal	Urticaria-like rash, arthropathy, neurological signs
Large Granular Lymphocyte leukemia	Somatic mutation in <i>STAT3</i> (GOF)	T or NK lymphocytosis with an activated phenotype	Normal	Normal	Neutropenia, anemia, splenomegaly
Hypereosinophilic syndrome	Somatic mutation in <i>STAT5B</i> (GOF)	Normal	Normal	Normal	Eosinophilia, atopic dermatitis, urticarial rash, diarrhea

AutoAb to IFN γ /susceptibility to mycobacteria

Mendelian susceptibility to mycobacterial disease (MSMD) is a rare inherited condition defined by selective susceptibility to weakly virulent mycobacteria, including Bacille Calmette-Guérin (BCG) vaccine substrains and various environmental mycobacteria, in otherwise healthy patients without overt immunological abnormalities. Patients with MSMD may also suffer from tuberculosis, caused by *Mycobacterium tuberculosis* or from invasive infections with intracellular-macrophage microorganisms, such as *Salmonella*. The genetic dissection of MSMD in these patients has revealed this condition to be caused by inborn errors of interferon (IFN)- γ immunity (Rosain et al., 2019). These findings confirm that IFN- γ is a critical macrophage-activating factor and most patients with MSMD have molecular defects in the IFN γ /IL-12 axis. Susceptibility to tuberculosis and nontuberculous mycobacterial infection as well as listeriosis, salmonellosis, histoplasmosis, coccidioidomycosis, melioidosis, and penicilliosis has been demonstrated in patients with IFN- γ R deficiency (Dorman and Holland, 2000). Mutations in 14 different genes, most of them impacting the same pathway, (*IL12B*, *IL12RB1*, *ISG15*, *TYK2*, *IRF8*, *SPPL2A*, *CYBB*, *IFNGR1*, *IFNGR2*, *STAT1*, *NEMO*, *RORC*, *JAK1*, *GATA2*) have been shown to cause MSMD (Rosain et al., 2019).

The first cases of immunodeficiency caused by autoantibodies to IFN- γ were described in 2004 (Döffinger et al., 2004; Höfllich et al., 2004). These reports have shown autoantibodies against IFN- γ associated with severe nontuberculous mycobacterial infections, mainly in female patients of East Asian descent. In a large series from Thailand and Taiwan, 81% of the 52 patients with disseminated nontuberculous mycobacterial infection had high titers of anti-IFN- γ autoantibodies (Browne et al., 2012). The prevalence was even higher (96%) in the 45 patients with other opportunistic infections (e.g., *Cryptococcus neoformans*, *H. capsulatum*, *P. marneffei*, disseminated salmonellosis or severe varicella-zoster virus infection). Overall, 88% of the patients with adult-onset immunodeficiency with opportunistic infections had anti-IFN- γ autoantibodies. These autoantibodies against IFN- γ in patients with disseminated nontuberculous mycobacterial infection were shown to be associated with two HLA class II subtypes; HLA-DRB1*15/16 and HLA-DQB1*05 (Pithukpakorn et al., 2015; Angkasekwinai et al., 2019).

AutoAb to IL-6/recurrent and severe bacterial skin infection

Increased susceptibility to staphylococcal diseases is observed in several PIDs, including chronic granulomatous disease, autosomal dominant hyper-IgE syndrome, anhidrotic ectodermal dysplasia with immunodeficiency and diseases associated with TLR signaling pathway deficiencies such as *IRAK-4*, *MyD88*, *IRAK-1* and *TIRAP* deficiencies. Infectious episodes are typically associated with mild or delayed signs of inflammation, such as fever and increase in C-reactive protein (CRP) levels as a consequence of an impaired production of proinflammatory cytokines such as IL-6, a cytokine that regulates the acute phase response in the liver, inducing production of C-reactive protein and other inflammatory markers.

Recurrent or severe skin infections involving *Staphylococcus aureus*, *Escherichia coli* or *Streptococcus intermedius*, have been described in a child and two adults in the absence of detectable serum CRP. The patients' serum contained high titers of neutralizing autoantibodies against IL-6, accounting for the lack of CRP response and, possibly, for the development of recurrent or severe infection (Puel et al., 2008; Nanki et al., 2013).

AutoAb to various cytokines/thymoma and good syndrome

Good syndrome is a rare sporadic condition with a late onset in which thymoma is associated with hypogammaglobulinemia. It is characterized by increased susceptibility to bacterial, viral and fungal infections, as well as autoimmunity. Most patients have no circulating B cells and defects in T cell-mediated immunity are frequently observed (Malphettes et al., 2015). Pathogenic autoantibodies are common in thymoma, most often in the form of myasthenia gravis caused by anti-acetylcholine receptor antibodies. Also described are a wide range of anti-cytokine autoantibodies, most commonly including IL-12 p35 and p40 subunits and type I interferons, but also other neutralizing anti-cytokine autoantibodies including those to IL-1 α , IL-17A, IL-22 (Burbelo et al., 2010). Lack of *AIRE* expression has been shown in thymoma tissue suggesting that beyond APECED, *AIRE* may play a role in other autoimmune conditions and contribute to the development of anti-cytokine autoantibodies, which are striking features of both APECED and thymoma (Offerhaus et al., 2007; Scarpino et al., 2007). It has been shown that in patients with thymoma, all patients with opportunistic infection had multiple anticytokine autoantibodies with blocking activity in vitro, suggesting that anticytokine autoantibodies may be important in the pathogenesis of adult-onset immunodeficiency associated with thymoma. The main cytokine targets for these autoantibodies were: IFN- α , IFN- β , IL-1 α , IL-12 and IL-17A (Burbelo et al., 2010).

AutoAb to GM-CSF/pulmonary alveolar proteinosis

Primary pulmonary alveolar proteinosis (PAP) is a rare syndrome characterized by accumulation of surfactant in the lungs that is mediated by disruption of granulocyte/macrophage colony-stimulating factor (GM-CSF) and alveolar macrophage dysfunction (Carey and Trapnell, 2010). Mutations or deletions in the GM-CSF Receptor alpha chain (*CSF2RA*) have been described in hereditary forms of the disease, reducing GM-CSF binding, receptor signaling, and GM-CSF functions in myeloid cells (Martinez-Moczygemba et al., 2008; Suzuki et al., 2008).

Autoimmune PAP accounts for approximately 90% of the PAP cases and is characterized by high levels of neutralizing GM-CSF autoantibodies (Inoue et al., 2008). This rare disease occurs in all ethnic groups and is approximately twice as common in males, presumably due to the association with smoking. Individuals usually present in the third to fourth decades of life with progressive dyspnea of insidious onset, diffuse bilateral lung infiltrates. Pulmonary alveoli are filled with a granular, eosinophilic, periodic acid-Schiff (PAS)-positive material. Secondary infections can occur and account for 18% of the reported mortality in PAP, presumably due to myeloid cell defects. The predisposition to infection is systemic, rather than confined to the lungs. Although organisms common in community-acquired infections have been reported in PAP (*Streptococcus*, *Haemophilus*, *Staphylococcus*, *Pseudomonas*), more often reports have identified unusual or opportunistic pathogens (*Mycobacteria*, *Aspergillus*, *Nocardia*, *Cryptococcus*) (Rosen et al., 2013).

AutoAb to C1 inhibitor/acquired angioedema

Hereditary angioedema (HAE) is a rare autosomal dominant disease due to C1 esterase inhibitor deficiency (C1-INH) (Zuraw and Christiansen, 2016). The disease is characterized by subcutaneous and submucosal edema in the absence of urticaria due to the accumulation of bradykinin (Agostoni et al., 2004). Acquired angioedema (AAE) is a very rare condition with a very similar clinical

phenotype (Cicardi and Zanichelli, 2010). Similar to HAE patients, patients with AAE have angioedema without urticaria. Angioedema recurs at unpredictable intervals, lasting from 2 to 5 days and presenting with disfiguring, nonpitting, non-pruritic edema of the skin (face, limbs, genitals), severe abdominal pain, life-threatening edema of the upper respiratory tract and edema of the oral mucosa and of the tongue. The only significant clinical difference between HAE and AAE is the age of onset of symptoms: before the second decade of life for more than 90% of patients with HAE, after the fourth decade for those with AAE. Angioedema of the gastrointestinal mucosa causing abdominal pain is less frequently reported in patients with AAE (Bouillet-Claveyrolas et al., 2003). Anti-C1-INH autoantibodies are responsible for functionally inactivation and/or increase catabolism of the protein. A component detected in some AAE patients corresponds to the anti-C1-INH autoantibodies and can be associated with low-grade lymphoma. Based on these findings, AAE is considered as a condition associated with different forms of abnormal B cell proliferation ranging from autoreactivity to malignant lymphoma (Cicardi et al., 2003). Whether the different degrees of lymphoproliferation found in AAE patients are evolutionary stages of the same process starting from expansion of anti-C1-INH autoreactive clone(s) has not yet been clarified. Although lymphoproliferative diseases represent the main group encountered in AAE and a direct pathogenic relationship between the two conditions cannot be questioned, SLE, different neoplasia and infections have also been described in association with AAE.

Diseases associated with somatic mutations

Somatic mutation in *TNFRSF6*/autoimmune lymphoproliferative syndrome (ALPS-sFAS)

Autoimmune lymphoproliferative syndrome (ALPS) is a genetic disorder characterized by early-onset, chronic, nonmalignant lymphoproliferation, autoimmune manifestations, and susceptibility to lymphoma. In ALPS, lymphocyte homeostasis is disrupted by defects in the apoptosis process mediated by Fas, a cell-surface receptor (CD95) from the TNF receptor superfamily. An excess of circulating TCR $\alpha\beta^+$, CD4 $^-$ CD8 $^-$ double-negative (DN) T lymphocytes and elevated plasma levels of Fas ligand (FasL), vitamin B $_{12}$, and IL-10 are diagnostic hallmarks of the disease. The majority of ALPS patients carry heterozygous germline mutations in the *TNFRSF6* gene coding for Fas (ALPS-FAS) (Neven et al., 2011). The penetrance of the disease in carriers ranges between 50 and 75%. The variable clinical penetrance of *TNFRSF6* mutations and the differing phenotype found in patients from the same family indicate that additional genetic or environmental factors determine the clinical manifestations of ALPS. Indeed, the additional presence of a somatic event impairing the second *TNFRSF6* allele (i.e., somatic mutation or duplication of the mutant allele with loss of the wild-type allele) have been described in patients with heterozygous germline mutation. Interestingly, patients with germline mutations and somatic changes in the second *TNFRSF6* allele were significantly older at disease onset than other ALPS-FAS patients, suggesting that the second “hit” may be acquired later in life.

In addition, somatic *TNFRSF6* mutations have been described in patients with an ALPS phenotype but no germline mutation in *TNFRSF6* (Holzelova et al., 2004). These dominant heterozygous Fas mutations are detected in the DN T cells. It represents the second most common genetic etiology of ALPS (ALPS-sFAS) as diagnosed in 12 out of a series of 31 patients with an ALPS phenotype but no germline mutation of the *TNFRSF6* gene (Dowdell et al., 2010). Similar to classic ALPS patients, the somatic ALPS patients had increased DNT cell numbers and elevated levels of serum vitamin B $_{12}$, interleukin-10, and sFAS-L. ALPS patients with somatic variants showed variable lymph node pathology. Most biopsies exhibit characteristic features of ALPS-associated lymphadenopathy, including expansion of DNTs, and in some patients, increased S-100-positive cells with emperipolesis resembling Rosai-Dorfman disease. These data support testing for somatic *TNFRSF6* mutations in DN T cells from ALPS patients with no detectable germline mutation and a similar clinical and laboratory phenotype to that of ALPS.

Somatic mutation in *KRAS* or *NRAS*/RAS-associated autoimmune leukoproliferative syndrome (RALD)

Ras-associated autoimmune leukoproliferative disorder (RALD) is a nonmalignant clinical syndrome initially identified in a subset of putative autoimmune lymphoproliferative syndrome (ALPS) patients. Similar to patients with ALPS, RALD patients present with lymphadenopathy, massive splenomegaly, increased circulating B cells, hypergammaglobulinemia, and autoimmunity (Takagi et al., 2011). In contrast to ALPS, biomarkers such as TCR $\alpha\beta^+$ CD4 $^-$ /CD8 $^-$ double negative T cells and serum vitamin B $_{12}$ levels are not always increased, and germline or somatic mutations in *FAS*, *FASL*, or *CASP10* are absent in RALD. Persistent absolute or relative monocytosis is a cardinal feature of RALD. Bone marrow and peripheral blood smear findings overlap with those of juvenile myelomonocytic leukemia (JMML) in children or chronic myelomonocytic leukemia (CMML) in older patients (Calvo et al., 2015).

Activating somatic mutations that cause amino acid substitutions that affect *KRAS* or *NRAS* were identified in myeloid and lymphoid lineages (Oliveira et al., 2007; Niemela et al., 2011). JMML is an aggressive malignant hematopoietic neoplasm of childhood with myelodysplastic and myeloproliferative features. Patients present with splenomegaly, fever, thrombocytopenia, monocytosis, and excess myelomonocytic cells that infiltrate skin and vital organs (Murakami et al., 2018; Niemeyer and Flotho, 2019). JMML accounts for 20–30% of myelodysplastic/myeloproliferative disorders in the pediatric population. The prognosis for JMML is poor with median survival of 1 year for untreated patients. Hematopoietic stem cell transplantation has become the standard of care for JMML. CMML has a variable course in adults and often requires chemotherapy. Distinguishing these conditions from RALD is critical.

Somatic mutation in NLRP3/cryopyrinopathy

The cryopyrin-associated periodic syndromes (CAPS) are a group of autoinflammatory disorders including familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and Neonatal-Onset Multisystem Inflammatory Disease (NOMID) also known as Chronic Infantile Neurological Cutaneous and Articular (CINCA). These dominantly inherited diseases are caused by heterozygous missense gain-of-function mutations in the *NLRP3/CIAS1* gene encoding NLRP3, also known as cryopyrin, leading to the activation of the inflammasome and overproduction of IL-1 β (Booshehri and Hoffman, 2019).

Somatic *NLRP3* mutations account for up to 70% of NOMID/CINCA patients who test negative for a germline mutation. Patients with somatic mutations present with symptoms comparable to patients with germline mutations, with slightly older age of disease onset and possibly milder CNS disease. The frequency of the mutant allele was reported to be similar in various cell types including myeloid cells, T cells and B cells and epithelial cells (Aróstegui et al., 2010; Tanaka et al., 2011; Rowczenio et al., 2017). A small number of monocytes carrying the *NLRP3* mutation are sufficient to evoke systemic inflammation. Two patients with the variant-type of Schnitzler syndrome have been reported with a myeloid lineage-restricted somatic mosaicism of *NLRP3* mutations (Rowczenio et al., 2018).

Somatic mutation in STAT3 or STAT5B (GOF)/large granular lymphocytosis

Large granular lymphocyte (LGL) leukemia belongs to the rare chronic mature lymphoproliferative disorders of the T/natural killer (NK) lineage (Lamy et al., 2017). T-LGL leukemia and chronic NK-cell lymphocytosis share the same clinical and biological presentation, as well as treatment options. Pathogenesis of the disease is dominated by a clonal expansion of LGL resistant to activation-induced cell death due to constitutive survival signaling. LGL leukemia principally affects elderly people with a median age of 60 years. Very rare pediatric cases have been reported. About one-third of patients are asymptomatic at the time of diagnosis. Initial presentation is mainly related to neutropenia and includes recurrent oral aphthous ulcerations and fever secondary to bacterial infections. These infections typically involve skin, oropharynx, and perirectal areas, but severe sepsis may occur. However, some patients may have profound and persistent neutropenia without any infections over a very long period of time. Splenomegaly is frequent and lymphadenopathy is rare. Most patients present with mild or moderate lymphocytosis with LGL usually ranging from 1 to $6 \times 10^9/L$. Severe neutropenia ($<0.5 \times 10^9/L$) is observed in 16–48% of cases. Anemia is frequent and sometimes secondary to pure red cell aplasia and moderate thrombocytopenia is less frequently observed (Ishida et al., 2014). The first diagnosis is based on identification of increased numbers of circulating LGL, easily identified on blood smears by their specific morphology; however, they are not cytologically distinguishable from normal reactive cytotoxic lymphocytes. T-LGL leukemias show a constitutive mature post-thymic phenotype. In the vast majority of cases, T-LGL leukemia shows a CD3⁺, TCR $\alpha\beta$ ⁺, CD4[−], CD5^{dim}, CD8⁺, CD16⁺, CD27[−], CD28[−], CD45RO[−], CD45RA⁺, and CD57⁺ phenotype, which represents a constitutively activated T cell phenotype. NK-LGL leukemia and NK-LGL lymphocytosis are characterized by the following phenotype: CD2⁺/sCD3[−]/CD3e⁺/TCR $\alpha\beta$ [−]/CD4[−]/CD8⁺/CD16⁺/CD56⁺. The transcriptome of LGL leukemia patients is that of *STAT3*-regulated genes suggesting that constitutive activation of *STAT3* plays a fundamental pathogenic role in LGL leukemia. Constitutive activation of *STAT3* in LGL leukemia patients was first discovered in 2001 (Epling-Burnette et al., 2001). In 2012, common somatic gain-of-function *STAT3* mutations were demonstrated in 28–75% of T-LGL leukemia and 30–48% of NK-LGL lymphocytosis. These differences may be due to the sequencing technique and the selection of patients (Jerez et al., 2012; Koskela et al., 2012). Detection of identical *STAT3* mutations in both T- and NK-subtypes suggests a unifying pathogenesis for these similar disorders. It has been suggested that a particular *STAT3* mutation, Y640F, predicted response to initial therapy with methotrexate. The first evidence of *STAT5B* mutations in human disease was discovered in LGL leukemia, but this mutation is not frequent (2%). The N642H mutation was associated with more aggressive disease and an unusual CD3⁺CD56⁺ phenotype.

Somatic mutations in STAT5B (GOF)/hypereosinophilic syndrome

Somatic, gain-of-function mutations in *STAT5* have been described in leukemias and lymphomas and, more recently the *STAT5B* N642H mutation has been reported in patients with hypereosinophilic syndrome (Cross et al., 2019). The syndrome associates eosinophilia, atopic dermatitis, urticarial rash and diarrhea. Additional clinical manifestations includes infections such as pneumonia and a measles-like illness after receiving the measles, mumps, and rubella vaccine in one girl (Ma et al., 2017). In most cases the syndrome was associated with a diagnosis of myelodysplastic/myeloproliferative neoplasia.

Conclusions

The conditions described here most likely represent just the beginning of conditions that will ultimately be identified as clinical comparable to inborn errors of immunity but driven by either somatic mutations or autoantibodies.

VZV	Varicella-zoster virus
WT1	Wilms tumor 1

Introduction

The principle of allogeneic hematopoietic stem cell transplantation (allo-HSCT) was first explored in the mid of the 1950s to overcome the aplasia induced by lethal radiation accidents. Experiments in mice rapidly showed that transplanting lethally irradiated mice with allogeneic hematopoietic stem cells (HSC) not only allowed engraftment of hematopoietic cells but was also associated, when leukemic cells were injected with the stem cell graft, with the development of an anti-leukemic effect called “graft versus leukemic effect” (GVL effect). However, allografted mice developed an immune mediated «secondary disease» called “graft-versus-host disease” (GVHD) (Granot and Storb, 2020).

In humans, the first case of leukemia cured by an allogeneic hematopoietic stem cell transplantation (allo-HSCT) performed between syngeneic brothers was reported by Donnall Thomas in 1957. Then this procedure had been expanded with the discovery of the HLA system at the end of the 1950s and the better knowledge of how to use it in the context of allo-HSCT in the aim to decrease the risk of GVHD. Because of the GVL effect, allogeneic HSCT is being used as curative treatment of leukemias since the beginning of the 1970s (Granot and Storb, 2020).

Nowadays, allo-HSCT is still the only potential curative treatment for some hematopoietic malignant and non-malignant diseases. Because the success of this therapy is still compromised by the development of the life-threatening GVHD, various immunosuppressive and immunomodulatory therapies are associated to prevent GVHD. However, cumulating these therapies with

long-lasting immunosuppressive effects may increase the incidence of malignancy recurrence and infections. Therefore, cellular strategies allowing more transient modulation of alloreactivity with regulatory cells are gaining interest in the field.

Post-transplant immune reconstitution

Immune reconstitution after allogeneic HSCT is a slow process requiring the development of a new immune system from the donor cells. If myeloid lineage reconstitutes in the first weeks following transplantation, the recovery of lymphoid cell subtypes, particularly of T and B cells, is affected by the use of immunocompromising drugs, affecting both recipient and donor immunity. These latter include the chemotherapy and/or total body irradiation of the conditioning regimen as well as *in vivo* T cell depleting agents such as anti-thymocyte globulin (ATG) or post-transplantation cyclophosphamide, that are required to allow HSC engraftment and prevent lethal GVHD. The deepness and length of these secondary humoral and cellular deficiencies are influenced by several factors such as the age of recipient, the source of HSC, the level of HLA disparity between donor and recipient, the intensity of conditioning regimen, the use and type of T cell depletion but also the occurrence of GVHD and the duration of immunosuppressive treatments (Ogonek et al., 2016).

With respect to lymphocyte deficiency, while the NK cell population reconstitution occurs within the first weeks after HSCT, T lymphocytes remain quantitatively and qualitatively deficient during the first 6–12 months post-transplant. The lymphocyte quantitative defect mainly concerns naïve and CD4⁺ T cells with a prolonged inversion of the CD4/CD8 ratio. Indeed, CD8⁺ T cells recover within the first 3–6 months. In addition, during the first year post-HSCT, T cell expansion is usually oligoclonal and the T cell repertoire diversity is poor and particularly affected in the case of the development of acute GVHD.

Recipient antigen presenting cells (APC) disappear during the first 6 months post-transplant while donor APCs have distinct recovery patterns. While monocytes reconstitution occurs in the first weeks post-transplant, dendritic cells (DCs) recover between 6 and 12 months after HSCT. A slow B cell reconstitution associated with severe and prolonged hypogammaglobulinemia is frequently observed during the first 6–12 months after transplantation (Fig. 1) (Ogonek et al., 2016).

Despite granulocyte recovery, the lymphocyte immune deficiency is responsible for a susceptibility towards infectious agents mainly viruses (HSV, CMV, VZV, EBV, HHV6, BK, Polyomavirus, Enterovirus, Respiratory viruses, Adenovirus), fungi (*Candida*, *Aspergillus*, *Pneumocystis jiroveci*, *Cryptococcus*, *cryptosporidium*), some encapsulated bacteria (*Streptococcus pneumoniae*, *Haemophilus*, mycobacterias) and parasites (*Toxoplasma gondii*) (Fig. 2A). The risk of infection or reactivation is increased in case of occurrence of GVHD requiring prolonged immunosuppressive therapies and is dependent on the level of CD4 T cell recovery (Fig. 2B) (Ogonek et al., 2016).

The graft versus leukemia (GVL) effect

Proof of concept

The demonstration of the role of donor T cells in the generation of the life threatening GVHD led to perform T cell depleted allogeneic HSCT. If this approach could effectively reduce the risk of acute GVHD, the strategy was also associated with higher incidence of disease relapse. The anti-leukemic effect of allogeneic HSCT was also suggested by higher leukemia response rates observed in patients receiving an allogeneic HSCT rather than a syngeneic HSCT. In addition, the possibility of achieving disease control after administration of donor lymphocyte infusions (DLI) in patients relapsing with chronic myeloid leukemia following allogeneic HSCT confirmed the role of donor T cells in the induction of the GVL effect (Dickinson et al., 2017).

Fig. 2 (A) Potential infections after allogeneic HSCT. (B) Risk of infection/reactivation according to CD4 T cell counts after allogeneic HSCT.

Initially demonstrated in leukemias, the GVL effect has also been shown in other hematological malignancies. Therefore, pre-emptive DLI (performed in case of detectable minimal residual disease (MRD) and/or of mixed chimerism status) have been well studied to improve patient outcomes. This approach induces a high rate of conversion from mixed chimerism to complete chimerism and allows durable remissions with a risk of developing GVHD (Dickinson et al., 2017).

Immunological mechanisms

Several subsets of immune cells and immunological mechanisms are involved in the graft versus leukemia/tumor effect (Dickinson et al., 2017).

Antigen presenting cells

A large pool of potential APCs can be considered including normal subsets of DCs, leukemia-derived DCs, B cells, macrophages and leukemic cells themselves. It has been demonstrated in mice that host APCs can present allo-antigens and tumor associated antigens and thus are able to trigger naïve CD4⁺ and CD8⁺ T cell primed and licensed to kill (Fig. 3). Moreover, donor-derived APCs are able to take over the GVL effect by inducing long term anti-tumor responses, particularly if the tumor burden is low.

Fig. 3 Mechanisms of graft versus Leukemia effect.

T cells

Both donor CD4⁺ and CD8⁺ T cells are required for the GVL response. This observation led to investigate which allo-antigens could be involved in the immunotherapeutic effect of allogeneic HSCT. Gene polymorphisms between donor and recipient induce differences in sequences of homologous peptide derived proteins that are called minor histocompatibility antigens (mHa). These class I or class II MHC-restricted epitopes can be recognized by donor CD8⁺ or CD4⁺ specific T cells and can eradicate leukemic cells after experimental adoptive transfer. Currently, three classes of allo-antigen are described:

- First, tissue restricted mHas like HA-1, HA-2, HB-1, BCL2A1 or LRH-1. These antigens are only expressed on hematopoietic cells and should not induce GVHD. Specific CTLs for these antigens have been found in patients after allo-HSCT or DLI in correlation with responses against leukemic cells. Moreover, HB-1 and BCL2A alloantigen specific CTLs can induce in vitro the lysis of leukemic cells.
- Second, ubiquitously expressed mHas. These antigens, such as HA-8 and UGT2B17 can be involved in the GVHD and/or GVL effects depending on their tissue expression. LRH-1 represents an interesting target due to its preferential expression on CD34⁺ leukemic cells, which might explain the low incidence of GVHD in patients with LRH-1 specific CTLs.
- Third, tumor associated antigens (TAAs). These antigens can be proteins aberrantly expressed on tumor cells such as WT1, Proteinase 3 or Survivin. Despite their expression in normal tissues, TAAs overexpression could allow T cells to discriminate between normal and tumor cells, and bypass natural tolerance to self-antigens, which explains that TAA specific CTL generation correlates with a better outcome. Some trials of WT1-based vaccination have reported vaccine-induced immunological and clinical responses. Other tumor antigens are malignant-cell-restricted proteins generated either from chromosome translocations or gene mutations, for instance NPM1 or internal tandem duplication of FLT3. Such tumor specific mutated proteins can also be recognized by the immune system. These allo-antigens are interesting targets because they can induce specific CTLs in vitro with cytolytic activity against leukemic but not normal CD34⁺ cells in patients.

Different cytotoxic mechanisms leading target cell killing by T cells have been recognized: CD8⁺ cytotoxic T-cells (CTL) mainly use perforin/granzyme degranulation following TCR-mHa/MHC Class I binding. CD4⁺ T cells, besides their helper function in producing IL-2 (interleukin 2) and IFN- γ (Interferon gamma), can also act as CTLs by the release of perforin. Other cytotoxic pathways have been reported such as Fas/FasL or membrane-anchored or soluble TNF α via TNF-receptors but their implication in the induction of the GVL effect in humans remains to be demonstrated (Fig. 3).

NK cells

Natural Killer (NK) cells are characterized by their capacity to kill target cells such as tumor cells depending on their expression of killer-cell immunoglobulin-like receptors (KIRs), which recognize activating or inhibitory ligands expressed on target cells.

The signal induced by the recognition of inhibitory KIRs (for instance CD94/NKG2A) by inhibitory ligands, mainly HLA class I molecules, leads to the inhibition of the cytotoxicity of the NK cell. After specific ligand recognition, the signaling through activating KIRs (for instance CD94/NKG2C and NKG2D recognize the stress induced MIC-A and MIC-B molecules on tumor or infected cells) induce the lysis of the target cell. The expression of activating receptors and ligands can be upregulated in the context of inflammation or stress such as in viral infections or in tumors. NK cells will kill a target cell either in the absence of inhibitory signals (HLA class I missing) or in the presence of a relative higher expression of activating ligands (inflammation/stress) (Fig. 3).

The implication of NK cells in the GVL effect was first suggested in the context of haplo-identical HSCT in the presence of HLA class I mismatch. The main HLA epitopes involved in cytotoxicity are HLA-C1, C2 and Bw4. In this setting, the GVL is driven by donor NK-cell expressing KIRs not inhibited by the recipient HLA class I molecules (recipient missing the inhibitory KIR ligands). In this context, KIR mismatched NK cells might also kill recipient APCs and hematopoietic stem cells and thus reduce the risk of GVHD and facilitate engraftment (Ruggeri et al., 2002).

Because KIR and HLA genes are localized in distinct chromosomes (chromosome 19q13.4 and 6p21, respectively) and thus segregate independently, an HLA matched donor-recipient pair can be KIR-mismatched. More recent studies exploring NK alloreactivity on transplant outcomes has then been performed in matched unrelated HSCT (MUD). However, in this setting, the role of the KIR-ligand mismatches on the risk of disease relapse is still controversial.

Immune evasion

Accumulating evidence recently suggest that disease relapse after allo-HSCT is mediated by tumor cell escape to the alloreactive immune response (Zeiser and Vago, 2019). Because donor cell exhaustion has been observed in relapsing patients, immune checkpoint blockade has been shown to be able to improve the antitumor effect of allo-HSCT with a risk of inducing severe acute GVHD. Recent studies have demonstrated that relapse post-HSCT is associated with dysregulation of adaptive and innate immunity, including down-regulation of major histocompatibility complex (MHC) class II molecules inducing a permissive environment to promote T cell immune evasion in myeloid and lymphoid malignancies. Higher proportion of early-differentiated Memory Stem (T_{SCM}) and Central Memory T cells expressing multiple inhibitory receptors on their cell surface (PD1, Tim3, LAG3...) with impaired functions have been observed in patients relapsing after allo-HSCT. Reduced cytotoxic capacities of anti-leukemic effector T cells have been correlated with metabolic alterations such as decrease in glycolytic and oxidative metabolisms associated with impaired effector cytokine production (such as IFN- γ and TNF- α) (Zeiser and Vago, 2019).

Graft versus host disease

Two distinct clinical presentations of graft versus host disease are described (Ferrara et al., 2009). Acute graft versus host-disease usually occurs in the 3–6 first months post-transplantation and is characterized by acute organ toxicity mainly involving the skin, the gastro-intestinal tract and the liver. Chronic GVHD classically develops after 3 months post-transplant and presents features of auto-immune diseases with inflammatory and fibrotic features. The chronic form of the disease can affect multiple organs most frequently the skin and subcutaneous connective tissues, lacrimal and salivary glands, oral mucosa, lungs, gastrointestinal tract, liver and joints.

Immunobiology of acute GVHD

The “3 phases”

The immunopathophysiology of GVHD has been essentially explored in mouse models in which it has been classically described in 3 phases (Fig. 4) (Zeiser and Blazar, 2018).

In the first phase, the chemotherapy and radiation used for transplant conditioning induce tissue damages, particularly in the gut, associated with epithelial cell destruction and endothelial inflammation leading to the release of inflammatory signals (cytokines such as TNF- α , damaged tissue release DAMPs, microbial flora release PAMPs including LPS and CpG). Such inflammatory signals induce the maturation and activation of recipient APCs, characterized by the up regulation of surface co-stimulatory molecules, the production of cytokines and the capacity to migrate to secondary lymphoid organs.

The second phase takes place in secondary lymphoid organs where fully mature recipient APCs present a broad spectrum of antigens (major or minor histocompatibility antigens) to donor T lymphocytes. Activated APCs and T lymphocytes produce pro-inflammatory cytokines that include IFN- γ , TNF- α , IL-2, IL-12, IL-18, IL-21 and IL-17. This “cytokine storm” induces the activation of a large spectrum of other immune cells (NK, monocytes, macrophages). Alloreactive T cells can acquire the expression of specific tissue homing molecules and migrate towards inflamed GVHD target tissues (skin, GI, liver).

In the third phase, inflamed GVHD target tissues attract polynuclear cells, monocytes, mast cells, macrophages, and activated donor T cells that release several inflammatory cytokines enhancing the immune response. Host epithelial and endothelial cells can be attacked and destroyed by cytotoxic molecules released by activated macrophages and T cells, such as TNF- α , IFN- γ , IL-1 and azote monoxide (NO) and by alloreactive cytotoxic T cells expressing or secreting death molecules (Fas-L, Perforin).

Fig. 4 Pathophysiology of acute GVHD.

Role of conditioning, danger signals and microbiota

The conditioning regimen performed to allow the engraftment of donor allogeneic stem cells is usually based on chemotherapy or radio-chemotherapy, both of which induce tissue damages and the release of “danger signals.” This phenomenon is classically attributed to the release of inflammatory cytokines, tissue and microbial release proteins (DAMPs and PAMPs such as CpG and LPS) from injured, stressed, or dying cells and bacteria, in particular in the gastrointestinal tract. Those bacterial-derived and cellular danger components signal via toll-like receptors (TLRs) or NOD-like receptors (NLR) expressed on APCs. Gut microbiota play an important role in the regulation of GVHD (Fredricks, 2019). Microbiota diversity can be strongly impaired after allo-HSCT secondary to conditioning regimen and the frequent use of broad-spectrum antibiotics. A disequilibrium with loss of butyrate producing bacteria and other beneficial commensals associated with a relative increase in pathogenic bacterial such as *Enterococcus*, *Klebsiella*, *Escherichia*, *Staphylococcus* and *Streptococcus* has been described in allografted mice and patients. Colonization, before allo-HSCT, by multi-drug resistant bacteria and *Clostridium difficile* have been correlated with a higher risk of developing acute GVHD. Enterococcal expansion has been described in patients developing acute GI GVHD. Reduction of blautia, a clostridial specie producing butyrate, has been associated with increased mortality due to GVHD. This microbiota disequilibrium induces the activation of APCs through TLRs increasing T cell stimulation and innate cell recruitment but also reduces GI epithelium integrity (loss of protection by butyrate, reduction of protective mucus . . .) and enhances the destruction of Paneth cells explaining the sera increase in antimicrobial peptides (AMPs), such as Reg3 α , that play a crucial role in the regulation of the equilibrium between activated and regulatory T cells in the mucosa (Fredricks, 2019).

Role and origin of antigen presenting cells

There are multiple types of APCs in diverse anatomic locations and with various recirculatory patterns that could be implicated in activating allogeneic T cells.

Professional APCs include dendritic cells, macrophages and B lymphocytes and have the capacity of antigen uptake, processing, and so-called direct presentation of peptides on major histocompatibility complex (CMH) class II to CD4 $^{+}$ T lymphocytes. Among those, DCs are not only the most efficient in direct presentation but also have the specific ability to cross present soluble antigens on CMH class I to CD8 $^{+}$ T lymphocytes.

DCs represent a heterogeneous population, schematically composed of two main distinct subtypes: conventional and plasmacytoid DC.

Conventional lymphoid DCs reside in lymphoid organs such as lymph nodes, spleen and thymus and lack migratory properties. By contrast, some conventional migratory dendritic cells are found in peripheral tissues such as skin, lung, intestinal tract, liver, and kidney. They are characterized by their unique ability to acquire antigens and subsequently migrate to the draining lymph nodes, where they interact with T cells. Among those, within the skin, Langerhans cells (LCs) and dermal DCs have a particular slow turnover and prolonged half-life.

Plasmacytoid DCs (pDCs) comprise a distinct DC subset found both in lymphoid and non-lymphoid organs and are characterized by rapid production of type I interferon in response to viral infections and the ability to differentiate into mature DC with high T cell stimulatory activity.

Several studies have been performed to determine which subsets of APCs are implicated in the activation of allogeneic T cells. In terms of subsets of APCs, circulating DCs and pDCs rapidly acquire a full donor chimerism, suggesting that circulating recipient's APCs are rapidly replaced by donor's ones. By contrast, a consistent pool of recipient LC and dermal DC can survive within weeks after allogeneic HSCT, even after myeloablative conditioning regimen, in humans and animal models. These different DC subsets have been reported from murine models to be the main players, rather than B cells and macrophages, in the induction of GVHD. A role of pDCs has been suggested in humans since patients with skin or intestinal acute GVHD have an increased infiltration of pDCs in those GVHD target organs.

In terms of origin of APCs, there is strong evidence in murine models for a crucial role of host's APCs in donor T cell allogeneic activation and effector differentiation, essentially via the direct presentation of recipient antigens to donor T cells. Other experimental data have also demonstrated a minor role for donor APCs cross presenting host antigens in initiating acute GVHD. However, these could drive further tissue injuries and exacerbate GVHD or pave the way for the installation of chronic GVHD (cGVHD).

Besides professional APC, there is growing evidence that non-hematopoietic cells can acquire a significant role in antigen presentation and the capacity to trigger alloreactivity, especially in an inflammatory context such as in the allogeneic HSC transplant setting. Among candidates, MHC II⁺ myofibroblasts and epithelial cells within the gastrointestinal tract, stellate cells within liver, especially intra-hepatic Ito cells and endothelial cells seem to be involved even if the extent of their implications in GVHD remains to be fully characterized.

To increase the complexity of the process, in some cytokine environment, some tolerogenic DCs can emerge. Those can present antigens without co-stimulatory molecules or deliver inhibitory signals driving immune tolerance. Indeed, they can produce T-cell inhibitory cytokines such as IL-10 and TGF- β , induce T cell anergy and/or generate regulatory T cells. Although induced regulatory/tolerogenic DCs can control GVHD in mice, their physiological role in the context of human allogeneic HSCT is unknown (Stenger et al., 2012).

Role of T cell subsets

Both the CD4⁺ and CD8⁺ T cells are involved in the pathobiology of acute GVHD. The CD4⁺ counterpart has a predominantly helper function but can also become cytotoxic, while the CD8⁺ counterpart is mainly cytotoxic.

In murine experimental models, naive CD3⁺CD44⁻ or CD62L⁺ and CCR7⁺ T cells exacerbate acute GVHD lethality while memory CD3⁺CD44⁺ or CD62L⁻CCR7⁻ protect mice from GVHD. In humans, a relative higher proportion of CCR7⁺ naive CD3⁺T cells in the stem cell graft has been associated with an increased risk of acute GVHD.

Depending on the cytokine context, murine and humans CD4⁺ T cells can differentiate into Th1, Th2, Th-9, Th17, Th22 or T regulatory cells. In experimental murine models of GVHD, naive alloreactive CD4⁺ T cells predominantly differentiate into Th1 cells, but a portion of them also differentiate into Th2 or Th17 cells. Th1 differentiation leads to tissue damage in the gut and liver, while Th2 and Th17 differentiation induces tissue damage in lung (mainly Th2) and skin (predominantly Th17). Down regulation of Th1 differentiation induces an increase in Th2 and Th17 responses responsible for an exacerbation of lung and skin GVHD while sparing the gut and vice versa. In addition, IL-22 producing T cells have been shown to protect mice from gut GVHD. In humans, the respective role of CD4⁺ Th differentiation remains poorly explored. Th1 and Th17 signatures have been observed in acute GVHD, while increased Th2 T cells in the stem cell graft is associated with a reduced risk of aGVHD.

Role of homing molecules and tissue specific receptors

Grafted T cells first transit through secondary lymphoid organs where they encounter APC before taking a direction to a specific target organ. In that context, lymph node homing markers (CCR7 and CD62L) are of major importance. Murine models of ASCT confirmed that CCR7^{-/-} T cells were not competent to induce GvHD and blockage of CD62L could reduce GvHD. In humans, adoptive transfer of CD62L⁺ T cells in MHC-mismatched recipients could reduce the risk of GvHD.

CCR5, a chemokine involved in migration to both lymph nodes and target organs including gastro-intestinal tract, has been extensively studied in murine models of ASCT. CCR5 polymorphisms have been shown to influence the risk of GvHD in patients.

Many selectins, integrins and chemokine receptors have been described in the migration of T cells towards peripheral tissues. Migration of donor T cells to gut-associated lymphoid tissues is dependent on the integrin α 4 β 7 and its ligand Mucosal Addressin Cell Adhesion Molecule (Mad-CAM). The integrin CD103 (the ligand of epithelial cell-specific E-Cadherin) has been implicated in the migration and cytolytic function of gut-infiltrating CD8⁺ lymphocytes during GvHD. Migration of lymphocytes to skin is directed by CLA, a ligand of E-selectin which is constitutively expressed on human dermal microvasculature and further increased by inflammation. The molecular effectors of lymphocyte migration to the liver in acute GVHD is more obscure although some evidence suggest the implication of integrin α 4 β 1 (VLA4), CCR5, and CD44.

Role of immunoregulatory cells

Allogeneic activation of donor T cells can be controlled by several immunosuppressive cell subsets (Fig. 5).

Regulatory T lymphocytes

A subset of CD4⁺T cells deriving from the thymus, named the natural T CD4⁺CD25^{high}FoxP3⁺ regulatory lymphocytes (T regs), can inhibit the proliferation of alloreactive T cells in vitro and can separate GVH and GVT in mouse models of allogeneic HSCT. T regs inhibit the interaction between APCs and T cells by different mechanisms: (i) by contact dependent-means mainly via their expression of CTLA4, which inhibits the interactions APC/T and induces indoleamine 2,3-dioxygenase (IDO), an inhibitor of T

Fig. 5 Immunoregulatory cells implicated in the regulation of GVHD.

cell activation and proliferation, (ii) by competitive uptake of IL-2 and (iii) by the production of immunosuppressive cytokines such as IL-10 and TGF-β.

In humans, natural T regs are defined as CD4⁺CD25⁺FoxP3⁺CD127^{low} T cells. Inducible T regulatory type 1 (Tr1) cells are characterized by the co-expression of CD49b and lymphocyte-activation gene 3 (LAG-3) and the ability to secrete IL-10, TGF-β, and granzyme B, in the absence of IL-4 and IL-17. The chief mechanisms by which Tr1 cells control immune responses are secretion of IL-10 and TGF-β and killing of myeloid cells via Granzyme B. The possibility to generate and expand Tr1 cells in vitro in an Ag-specific manner has led to their clinical use as cell therapy in patients.

A subgroup of CD4⁺CD8⁺CD3⁺TCRαβ⁺ T cells can inhibit alloreactive T cell functions in mice and humans by trogocytosis of APCs' alloantigens, reduction of the expression of co-stimulation molecules CD80/CD86 on DCs and induction of CD8 T cell apoptosis by Fas/FasL. They can control experimental GVHD in mice. Their role in human GVHD is unknown (Hefazi et al., 2021).

γδT cells

They represent a subgroup of T cells expressing a γδ-TCR specialized in the recognition of heat shock proteins from tumor cells and some non-peptidic ligands. They are present in epithelial tissues and implicated in the innate anti-infectious and tumor immunity by their production of high amounts of IFN-γ and TNF. They also express some KIR, which enable them to kill target cells.

Some experimental data suggest a beneficial role of γδ T cells on the separation of GVH/GVL. An improved post-transplant reconstitution of γδ T cells in patients has been associated to a significant reduced risk of relapse without increasing the risk of GVHD but the mechanisms involved in their regulatory functions are unknown.

Invariant NKT lymphocytes (iNKT)

iNKT cells represent another immunoregulatory T cell population characterized by the expression of a TCR molecule composed of an invariant Vα chain (mVα14/hVα24Jα18) associated to a limited repertoire of Vβ chains. These cells recognize glycolipids presented by the CD1d molecule. They can produce, upon stimulation either by their TCR signal or in response to inflammatory cytokines (IL-12, IL-18, IL-33), important amounts of cytokines (Th-1, Th-2 or Th-17) and drive the immune response towards

tolerance or the elimination of pathogens or the removal of tumor cells. iNKT cells can also separate GVH et GVT in mouse models by the induction of Th-2 immune responses and the expansion of T regs (Kohrt et al., 2010).

An enhanced early post-transplantation recovery of total iNKT cells has been associated with reduced risk of acute GVHD while sparing the GVL effect (Rubio et al., 2012). A higher content of the stem cell graft in CD4⁺ iNKT cells has been reported to be associated with a reduced risk of acute GVHD (Chaidos et al., 2012). Altogether, these data argue for a regulatory role of iNKT cells in the control of GVHD. In a preclinical model of xeno-GVHD, CD4⁺ iNKT cells have been shown to be able to regulate GVHD by killing recipient APCs and therefore reducing alloreactive T cell activation (Rubio et al., 2012). In T cell depleted haplo-identical HSCT in pediatric ALL, the reconstitution of iNKT cells was inversely correlated with the risk of relapse suggesting a role for iNKT in the GVL effect.

Mesenchymal stem cells (MSC)

MSCs are a heterogeneous population of multipotent, self-renewing progenitors, that can be differentiated in adipocytes, chondrocytes, and osteocytes. They may be isolated from many adult and fetal tissues, particularly bone marrow (BM-MSCs), adipose tissue, dental pulp, amniotic fluid, embryonic placenta, umbilical cord, and other tissues. MSCs from various origins can suppress the activation and functions of most of the immune cells involved in the pathophysiology of GVHD (T cells, B cells, NK cells, monocytes, DCs). They display low immunogenicity in vitro, reason why they are studied as allogeneic adoptive cell therapy.

MSCs can inhibit T cells by cell contact interaction involving several molecules expressed on MSCs (particularly programmed death ligand 1 and 2, HLA-G, Galectin-1), and by the production of immunosuppressive mediators and metabolic changes (particularly tryptophan depletion and tryptophan metabolites via indoleamine 2,3 deoxygenase (IDO) activation, Transforming Growth Factor TGF- β , Hepatocyte Growth Factor, Prostaglandin E2, heme-oxygenase-1, leukemia inhibitory factor, and adenosine).

In addition, MSCs can modulate T cell functions by skewing Th-1 T-cell responses towards Th-2 T-cell responses, but also by the induction of CD4⁺CD25⁺Foxp3⁺ T cells (T regs) and the inhibition of naive CD4⁺ T differentiation into Th-17 cells. Moreover, MSCs impair the differentiation and maturation of monocytes and DCs and induce the generation of regulatory DCs such as plasmacytoid DCs. In vivo, allogeneic MSCs probably do not live long and could be killed by cytotoxic CD8⁺ T cells, and quickly phagocytosed. Their phagocytosis could lead to a key mechanism of immune modulation in vivo, by the development of anti-inflammatory monocytes which produce IDO. In patients, BM-MSCs have shown promising results to treat severe acute GVHD in children and adults. Other sources of MSCs (placenta and umbilical cord notably) are on clinical development to prevent or treat GVHD (Zhao et al., 2019).

Myeloid-derived suppressor cells (MDSCs)

In the late 1970s, a suppressive cell population, called "natural suppressor cells", was first identified in murine and rat bone marrow, spleen, and lymphatic tissues. These cells displayed an ability to suppress T-cell responses in vivo and in vitro without regard to the typical restrictions imposed by the major histocompatibility complex (MHC). Nowadays, MDSCs represent a heterogeneous group of cells. Based on the expression of CD49d, two distinct subpopulations have been described in mice: the first was the monocytic CD49d⁺ subpopulation, which also displayed CD11b⁺ Ly6C⁺ Ly6G^{low} CD115⁺ and the second was the granulocytic CD49d⁺ counterpart, which displayed CD11b⁺ Ly6C⁺ Ly6G^{high} CD115⁺. In humans, three distinct MDSC subsets have been described, based on monocytic, granulocytic, and early-stage characteristics. They commonly do not express markers of mature myeloid and lymphoid cells (lineage negative). Thus, monocytic human MDSCs (M-MDSCs) are defined as: CD11b⁺CD33⁺ HLA-DR^{low/-} and CD14⁺; granulocytic MDSCs (G-MDSCs) are defined as: CD11b⁺ CD33⁺ HLA-DR^{low/-} CD15⁺ but CD14⁻; and early-stage MDSCs (called e- or P-MDSCs) are defined as: CD33⁺ CD11b^{low} HLA-DR^{low/-} CD14⁻ CD15⁻. MDSCs are mainly defined by their capacity to inhibit the proliferation of allogeneic T cells. To date, these immunosuppressive properties have been attributed to five main mechanisms demonstrated in vitro and in vivo, including: NO production; arginase 1-mediated L arginine depletion; indoleamine 2,3-dioxygenase (IDO)-mediated tryptophan (an essential amino acid) conversion; and T regulatory lymphocyte (Treg) induction and reactive oxygen species (ROS) production. MDSCs can prevent GVHD while preserving the GVH effect in mouse models. Their role and potential impact on the GVL effect in humans is still debated (D'Aveni et al., 2020).

Regulatory B lymphocytes (B regs)

B cells derived from precursor cells that mature in the bone marrow. Briefly, immature B cells acquire B-cell receptors (BCRs) on their surfaces and undergo negative selection to delete or edit self-reactive B cells. Nonreactive immature B cells proceed through the circulation to the spleen and become transitional B cells, retaining high levels of immunoglobulin M (IgM) on their surfaces. In the spleen B-cell follicle, transitional B cells change into mature B cells and translate to the peripheral blood. B cells that have not encountered antigens are called naive B cells. In blood circulation, mature B cells receive stimulation from exogenous antigens and migrate towards lymphoid follicles as a result of germinal centre (GC) formation. In the GC, B cells interact with antigens presented by follicular dendritic cells, and B cells with low affinity move towards apoptosis, while high-affinity B cells proceed to plasma cells or memory B cells. This process is called positive selection. A subset of human and mouse B lymphocytes producing IL-10, named B-regs, has been reported to downregulate innate and adaptive immunity, inflammation, and autoimmunity. Since the first description, multiple subsets of B-regs, often with overlapping surface markers but diverse functions, have been reported. Among them, we can cite:

- CD19⁺CD24^{high}CD38^{high} B cells play immunosuppressive roles by retaining Tregs as well as limiting T-helper type 1 (Th1) and Th17 differentiation.
- CD24^{high}CD27⁺ and CD27^{high}CD38^{high} plasmablast B-cell compartments play roles in inhibiting monocyte activation and cytokine production from CD4⁺ T cells.
- CD73⁻CD25⁺CD71⁺ human B regulatory could produce IL10.

In mouse models, B-reg reduction are observed in sclerodermic chronic GVHD and decreased numbers of lymphoid progenitors and immature B cells in bone marrow are observed in the bronchiolitis obliterans syndrome (BOS). In patients with chronic GVHD, significant differences in their B-cell subsets are described. Circulating pre-GC B cells (IgD⁺CD38^{high}CD27⁺) and post-GC “plasmablast-like” cells (IgD^{low}CD38^{high}CD27⁺) increase along with elevated BAFF in a BAFF-dependent way and can produce antibodies without the help of BCR or secondary signal stimulation (Li et al., 2019).

Immunology of chronic GVHD

The pathophysiology of chronic GVHD (cGVHD) has been also described in 3 phases (Fig. 6) (Chaidos et al., 2012). During the first phase, the conditioning regimen induces the destruction of epithelial thymic cells. Thymic damage leads to both defective negative selection of auto- and allo-reactive T cells that can support a reduction in the number or function of regulatory cells such as Tregs and a pathogenic B-cell development. In addition, thymic damages and reduction in regulatory cells are aggravated by the emergence of alloreactive T cells in case of acute GVHD occurrence. In the second phase, B cells become potent antigen-presenting cells, mature, and gain the functional capacity to process and present minor histocompatibility antigens for HLA-matched donor-recipient pairs to donor CD4 T cells. The induction of CD4⁺ T cell polarized towards TH2/TH17 subsets triggers B-cell maturation and production of B-cell survival cytokines (IL-21). During the third phase, T and B cells clonally expanded and resistant to apoptosis, traffic to chronic GVHD target organ sites where IL-13, IL-22, and IL-33 are released. They create a chronic inflammatory environment that can recruit macrophages which produce platelet-derived growth factor alpha (PDGF- α) and transforming growth factor beta (TGF- β) leading to fibrosis. The analysis of peripheral blood in patients suffering from chronic GVHD has shown an increase of (i) a factor implicated in the activation and survival of B cells (B cell activating factor of the tumor necrosis family, BAFF), (ii) high plasma BAFF levels and high BAFF/B-cell levels result in increased numbers of circulating pre-germinal center (GC) B cells and post-GC plasmablast-like cells, capable of producing donor-derived alloantibodies without antigen restimulation (iii) and a delay in reconstitution of naïve B cells (Zeiser and Blazar, 2017).

Fig. 6 Pathophysiology of chronic GVHD.

Therapeutic immune modulation

In clinical practice, the prevention and treatment of GVHD is based on the use of pharmacological agents mainly interacting with the activation of T cells by APCs (Penack et al., 2020). Such approaches have reduced the risk of developing acute and chronic GVHD and have allowed the development of mismatched allogeneic HSCT such as with partially matched cord blood units or haplo-identical HSC.

Conventional immunosuppressive agents

Immunosuppressive agents can interfere with at least one of the three signals implicated in the activation and proliferation of T cells following their interaction with APCs (Fig. 7). The first signal (signal 1) is mediated by the TCR stimulation which induces a cascade of intracellular protein phosphorylation leading to the activation of the serine threonine phosphatase calcineurin. This latter allows the dephosphorylation and activation of the transcriptional factor NFAT (nuclear factor of activated T cells). The NF- κ B pathway is also activated following TCR activation leading to the translocation to the nucleus of a transcription component. The latter induces the transcription of cytokines (predominantly IL-2), cytokine receptors (CD25 or IL-2R) and co-stimulation molecules (CD40L). The second signal (signal 2) is mediated by co-stimulation molecules expressed on APCs (CD80/86 and CD40) and their ligands expressed on activated T cells (CD28 and CD40L, respectively). The third signal (signal 3) is the consequence of the interactions between cytokines (IL-2, IL-15, IL-7) and their cognate receptors expressed on T cells. The stimulation of CD25 activates some janus kinases (Jak3/Stat5) and the mTor protein (mammalian Target of rapamycin), both of which regulate the progression from the G1 to the S phase of the cell cycle leading to T cell proliferation, which also requires functional de novo DNA synthesis.

Commonly used immunosuppressive drugs to prevent and treat GVHD are: inhibitors of calcineurin (cyclosporin and tacrolimus), inhibitors of the cycle cell or DNA synthesis (MMF, Methotrexate), inhibitors of mTOR (sirolimus or everolimus), steroids (inhibiting APC/T cell interaction and cytokine production by T cells as well as T cell homing to inflamed tissues), anti-JAK (ruxolitinib, itacitinib) and ibrutinib that inhibits the Bruton's tyrosine kinase.

In addition to pharmacological agents targeting T cell activation, there are monoclonal antibodies and immunosuppressive strategies. They include T and B cell depleting antibodies including anti-thymocyte globulin (ATG), anti-CD52 (mabcampath), anti-CD20 (rituximab), anti-IL2 receptor or anti-CD25, and extracorporeal photopheresis (ECP), an ex vivo therapy of leukapheresis collected lymphocytes by a psoralen sensitizer exposed to ultraviolet light and subsequently re-infused to the patient. This procedure induces apoptotic T cells, tolerogenic DCs and increased T regs.

In addition, cyclophosphamide, an alkylating agent, that triggers the apoptosis of activated T cells while sparing Tregs has more recently introduced into the different strategies of GVHD prevention.

Indeed, all patients receiving allo-HSCT will receive a combination of immunosuppressive drugs to prevent acute and chronic GVHD. A combination of two pharmacological inhibitors is usually used in ex vivo non-T cell depleted allo-HSCT: a calcineurin inhibitor targeting signal 1 (cyclosporin A or tacrolimus) in association with an inhibitor of signal 3 (either the anti-metabolite methotrexate or the inhibitor of purines mycophenolate mofetyl (MMF) or the mTor inhibitor rapamycin/Sirolimus).

Fig. 7 Mechanisms of action of usual pharmacological immunosuppressive drugs.

In addition, administration of ATG before HSCT has been shown to prevent severe acute and chronic GVHD and is recommended in matched or mismatched unrelated or related donors. In haploidentical allo-HSCT, different GVHD prevention are used but the most developed is the administration of high doses of cyclophosphamide in a narrow window after transplantation (days 3 and 4 or 5) instead or in combination with ATG (Penack et al., 2020).

The first line treatment of acute or chronic GVHD is based on the use of steroids. Currently, ruxolitinib (JAK2 inhibitor) is the only approved drug for the treatment of steroid refractory acute and chronic GVHD (Zeiser et al., 2020). In third line, there is no consensus of treatment. None of the immunosuppressive drugs previously cited have significantly improved the poor prognosis of steroid resistant acute GVHD (OS <40% at 1 year) or steroid resistant severe chronic GVHD (30–50% mortality at 5 years) (Toubai and Magenau, 2020).

Novel immunomodulatory approaches

The challenge of allogeneic HSCT is the development of novel immunomodulatory agents that can specifically target alloreactivity without impairing graft versus tumor beneficial effect. Maintenance therapies after allo-HSCT that specifically target the hematological malignancy to prevent their relapses can also prevent GVHD.

Tyrosine kinase inhibitors

- (i) Imatinib: Imatinib, the first tyrosine-kinase inhibitor developed to treat chronic myelogenous leukemia, is a potent dual inhibitor of both transforming growth factor- β and platelet-derived growth factor receptor (PDGF-R) pathways, 2 cytokines involved in the fibrogenic and inflammatory processes of chronic GVHD with systemic sclerosis.
- (ii) Ibrutinib: Bruton's tyrosine kinase (BTK) activation is critical for B-cell survival, proliferation, and migration. Ibrutinib was designed as a selective and irreversible inhibitor of the BTK protein and inhibits B-cell tumor growth such as chronic lymphocytic leukemia and B-cell lymphomas. In addition to inhibiting BTK, ibrutinib is an irreversible inhibitor of interleukin-2 inducible kinase (ITK) and is FDA-approved for the treatment of chronic GVHD.
- (iii) Itacitinib: A JAK1 inhibitor that reduces inflammatory cytokines and T cell proliferation. In a phase II trial, itacitinib seemed promising for the prevention of acute GVHD in addition to conventional GVHD prevention. A phase III in first line treatment of acute GVHD failed however to demonstrate an interest over steroids alone.

Belumosudil

An oral rho-associated coiled-coil-containing protein kinase-2 (ROCK2) inhibitor has been shown to reduce the Th-17 alloreactive response, increase T regs and control fibrotic pathways. Belumosudil treatment in a phase II randomized trial resulted in high response rates in steroid refractory chronic GVHD, improvement of quality of life and high overall survival rates. Belumosudil has been recently approved by the FDA for the treatment of chronic GVHD after failure of at least two prior lines of systemic therapy.

5-Azacytidine

The demethylating agent 5-azacytidine (AZA) has proven its efficacy in the treatment of myelodysplastic syndrome and acute myeloid leukemia. In mice, AZA improves both survival and GVHD severity. In humans, AZA significantly decreases human T-cell proliferation as well as IFN- γ and TNF- α serum levels, reduces the expression of Granzyme B and Perforin by cytotoxic T cells and might increase T reg proliferation therefore modulating alloreactivity (Fransolet et al., 2016).

Anti-BCL2

Venetoclax is a selective inhibitor of the anti-apoptosis factor B-cell lymphoma 2 (BCL2), which has been revealed to abundantly express in leukemia stem cells. Moreover, longitudinal analysis of T-cell transcriptomes in patients before the appearance of GVHD symptoms revealed the upregulation of anti-apoptotic regulator BCL2 at GVHD initiation. BCL2 RNA is elevated in multiple organs affected by GVHD and expression correlated with transplant-related mortality and steroid-refractory GVHD. Inhibition of BCL2 might induce apoptosis of alloreactive T cells and become a new targeted therapy in the treatment of steroid refractory GVHD.

Cellular immunotherapy

Besides pharmaceutical agents, the infusion of immunoregulatory cells appears an attractive option: they can control immune homeostasis, reduce detrimental T-cell responses to foreign antigens, facilitate tissue repair with believed short-lasting immune effects avoiding increase of relapse and infections (Voermans and Hazenberg, 2020).

Adaptive lymphoid cells: Regulatory T cells

In mice, it has been clearly demonstrated that freshly isolated donor T regs or ex vivo expanded T regs added to donor CD3⁺ T cells early after allo-HSCT reduced GVHD while maintaining the GVT effect. The ability of natural CD4⁺ CD25⁺ FoxP3⁺ CD127^{low} T cells to control GVHD while maintaining the GVT effect in humans is debated. The "first-in-man" infusion of in vitro expanded natural T regs were published in 2009 for the treatment of one acute and one chronic GVHD. Freshly isolated donor-derived T regs have been injected in prophylaxis of GVHD in some small series of mismatched cord-blood or haplo-identical HSCT and several clinical trials are still recruiting with diverse sources of T regs or purified Tr1 cells. There is however a concern about their possible inhibition of the GVL effect. Indeed, Treg depletion in donor lymphocytes injections (DLI) has been associated with enhanced anti-leukemic and

anti-lymphoma responses in patients relapsing after transplantation. A way of research to modulate GVHD without impairing the GVT effect by increasing natural Tregs in vivo could be obtained with $\alpha 1$ -Antitrypsin, a naturally abundant serine protease inhibitor, a new treatment testing in GVHD treatment, downmodulating inflammation and increasing ratios of regulatory (Tregs) to effector T cells (Teffs).

Innate lymphoid cells

Lymphoid members of the innate immune system include natural killer (NK) cells, innate lymphoid cells (ILCs), iNKT cells and $\gamma\delta$ T cells.

ILC type 2 (ILC2) and iNKT cells have been infused in preclinical models and shown to reduce GVHD. Improved iNKT reconstitution or increased iNKT cells in HSC grafts have been associated with reduced GVHD and relapse. Trials in humans with expanded iNKT cells are expected.

Donor NK cells also have been tested in preclinical models and in the clinic. Transfer of donor-activated murine NK cells reduced acute GVHD as they can eliminate host antigen-presenting cells (APCs), limiting donor T-cell expansion. In humans, however, a pilot study of patients given IL-15/4-1BB ligand-activated NK cells from HLA-matched sibling or HLA-matched unrelated donors showed that five of nine of the patients (55%) experienced aGVHD including three severe forms. Thus, NK cell therapies are mainly currently explored to treat or prevent relapse after allo-HSCT in high risk patients.

Higher donor $\gamma\delta$ T cell content in HSC grafts has been associated with increased incidence of acute GVHD. However, enhanced post-transplant $\gamma\delta$ T cell has been correlated to improved event-free survival and OS, particularly in T cell depleted haploidentical HSCT. Different strategies to enhance $\gamma\delta$ T cell recovery are used in the context of haploidentical HSCT in order to avoid GVHD while sparing the GVL effect.

Myeloid cells: MDSCs

Generating MDSCs for clinical applications might be difficult, because MDSCs represent a rare subpopulation of myeloid cells. To date, few researchers have proposed to expand MDSCs in vitro for cellular therapy. MDSCs can be expanded from cord blood unit or donor apheresis after G-CSF mobilization or steady state PBMC with a cocktail of cytokine including G-CSF $\pm$ GM-CSF $\pm$ SCF $\pm$ FLT3 $\pm$ IL-6. Few preclinical proofs of concept are available (D'Aveni et al., 2020).

Non hematopoietic cells MSCs

In humans, co-transplantation of MSCs with allogeneic HSC has been shown to prevent the development of acute or chronic GVHD. They also have been used for the treatment of high-risk and/or steroid refractory acute GVHD. Since the first successful treatment of acute GVHD by intravenous infusion of bone marrow-derived haploidentical MSC reported in a 9-year-old patient with severe resistant grade IV acute GVHD, similar results have been observed with MSCs from diverse sources (adult tissues including adipose tissue and extra-embryonic tissues such as placenta/umbilical cord and Wharton's Jelly). If no serious acute infusion-related toxicity and no serious treatment-related adverse events have been reported, controversial results on the potential of MSC to increase infection and relapse incidences have been reported. It is demonstrated that their immunosuppressive properties may vary with the donor of MSCs. To erase this high inter-individual variability some authors pool MSCs from eight voluntary donors and some teams license WJ-MSCs with pro-inflammatory cytokines, for instance IFN- γ , which improves their function to prevent GVHD (Pochon et al., 2022). We lack clinical imaging systems to determine how MSCs patrol after intravenous infusion and how long they do persist in vivo. Preclinical models demonstrated that 2 h after intravenous injection, MSC are in the lungs followed by an accumulation in the liver and spleen from 24 to 96 h following injection with a hepatobiliary and renal clearance and a probably very quick death after lung trapping, due to monocyte phagocytosis. That is why repeated infusions are now usually scheduled in clinical trial, with no data on the risk of HLA alloimmunization (Zhao et al., 2019).

Conclusion

The better understanding of the immune system regulation has provided better insight in the physiopathology of alloSCT. New therapeutic approaches for the prevention of graft versus host diseases has already led to cross the HLA barrier and expand donor availability for nearly all patients. In addition, the use of these new combined pharmaceutical and cellular approaches will allow a better control of GVHD without impairing the graft versus tumor effect, thus making allo-HSCT a safer and more efficient procedure to cure hematological and immunological disorders.

Introduction

Asthma is an impactful and common chronic pulmonary disease, affecting both children and adults, and one which disproportionately impacts ethnic minorities and people of low socioeconomic status (Akinbami et al., 2016). The most prevalent chronic respiratory disease globally, asthma is debilitating and potentially deadly, associated with hundreds of thousands of deaths annually and a significant burden in healthcare-associated costs and disability-adjusted life years (GBD Chronic Respiratory Disease Collaborators, 2017). The disease of asthma is inextricably tied up in, and potentiated by, the social determinants of health. Therefore, understanding the epidemiology of this disease is an important aspect in its management. Simply put, one cannot effectively manage an individual patient's asthma without engaging, on some level, with that patient's social, economic, and physical environment.

Asthma, as a clinical entity, defies easy definition. The complex nature of asthma pathophysiology and its myriad clinical manifestations makes concision difficult. One broadly encompassing definition of asthma is as *a chronic inflammatory disorder of the lungs causing generally reversible small airway obstruction*. The Global Initiative for Asthma (GINA) expands on this definition further:

Asthma is a heterogeneous disease, usually characterized by chronic airway inflammation. It is defined by the history of respiratory symptoms such as wheeze, shortness of breath, chest tightness and cough that vary over time and in intensity, together with variable expiratory airflow limitation.

(GINA, 2020)

The pathophysiology of asthma is not fully understood, but appears to be mediated by a complex interaction of pulmonary genetics, immunology, prenatal development and perinatal course; and is modulated further by environmental exposures, socioeconomic stressors, and adversity (Williams et al., 2009; Flanagan et al., 2018).

Epidemiology

The prevalence of asthma has increased globally since the mid-20th century, alongside an increasing burden of allergic disease, such as eczema and allergic rhinitis (Dharmage et al., 2019). Recent data indicates that this epidemic of asthma has perhaps plateaued in wealthier countries over the past decade; however, improvements in global asthma morbidity and mortality has stalled despite increased awareness of asthma and an ever-expanding armamentarium of asthma therapies (Akinbami et al., 2016; Ebmeier et al., 2017). Despite the higher prevalence of asthma in wealthier nations, low-middle income countries suffer a disproportionate mortality from the disease (Dharmage et al., 2019). Mirroring global inequities, historical segregation of communities in the United States of America (US) has contributed to severe and pervasive socioeconomic and health inequities which persist to this day (Williams et al., 2009). Chronic stressors, including exposure to violence, may confer increased susceptibility to environmental potentiators of asthma, such as poor air quality, through dysregulation of the autonomic tone of the airways (Wright et al., 2005). Recent US Centers for Disease Control and Prevention (CDC) National Health Interview Survey (NHIS) data from 2016 indicates that 1 in 12 children 0–17 years of age in the US has asthma, and suggests a slight decrease in asthma prevalence and the incidence

of asthma exacerbations since 2001 (Zahran et al., 2018). Despite this, asthma remains quite common and burdensome for US children, with an overall prevalence of around 8%, which is increased to about 10% for children at or below the federal poverty level (Zahran et al., 2018).

For many, asthma begins in early childhood (GINA, 2020). In children 5 years of age and younger, viral respiratory illnesses are a predominant cause of asthma exacerbation and wheeze; and with age aeroallergen sensitization becomes an increasingly important driver of asthma symptoms. Asthma with comorbid allergic disease, such as eczema, may confer a worse pulmonary function trajectory over time (Dharmage et al., 2019). Boys have a higher incidence of asthma than girls in early life; however, young women experience a proportionally higher burden of disease in adolescence (Dharmage et al., 2019). This shift persists into adulthood, where healthcare utilization and mortality is highest (Dharmage et al., 2019). For those patients with true adult-onset asthma, as much as 20% of disease is proximally attributable to chronic occupational exposure to inhaled irritants (Dharmage et al., 2019).

Manifesting as reversible bronchoconstriction of the small airways, acute asthma exacerbations (characterized generally by wheeze, shortness of breath, and increased work of breathing) are managed with bronchodilators and other medications, often inhaled, which modulate the muscular tone of the airways, easing the transit of air and ameliorating the obstructive defect for a time. Longitudinally, those patients with persistent asthma often require the use of daily immune-modulating medications such as inhaled corticosteroids (ICS) and leukotriene receptor antagonists. A subset of patients, perhaps as high as 8% by some estimates, experience severe asthma, as defined by symptoms which require high-dose ICS and a second, adjunctive controller to maintain symptom control, or asthma which is refractory to this maximal outpatient therapy (Dharmage et al., 2019). In those whose asthma is mediated by allergy and is particularly refractory to management, a burgeoning class of asthma biologic medications has been important.

Poorly-controlled and severe asthma may negatively impact childhood lung development, and adults with significant asthma may be at higher risk for the development of fixed airway obstruction and chronic obstructive pulmonary disease (COPD) over time (Dharmage et al., 2019; McGeachie et al., 2016). Importantly, the impact on childhood development is not only manifested in pulmonary disease and exercise limitation, as children with high disease burden are also at risk for behavioral and academic adversity, as well as anxiety and depression attendant to chronic disease (Schneider, 2020; Halterman et al., 2006). Similarly, adults may experience job instability and other economic hardship as a result of persistent asthma symptoms and lost productivity. Strikingly, employment instability itself is associated with incidence of asthma in adults (Loerbroks et al., 2014). Uncontrolled asthma may potentiate the health consequences of comorbid diseases, for example sickle cell disease and obstructive sleep apnea, and indeed in many cases these relationships may be bidirectional (Serrano-Pariente et al., 2017; Samarasinghe and Rosch, 2019). Smoking clearly contributes to the pathogenesis of asthma and COPD in some patients, as does the aforementioned occupational exposures (GINA, 2020).

Genetic risk factors

The overall prevalence of asthma has been increasing in the United States and throughout the developing world in recent decades (Moorman et al., 2012; Eder et al., 2006). The rise in asthma prevalence is driven by the complex interaction of genetic factors and multiple environmental risk factors. Early twin studies showed that genetic factors contribute to the development of asthma. Twin studies assess the heritable risk of a disease by comparing the rate of occurrence (concordance rate) among genetically identical monozygotic twins to genetically similar dizygotic twins. Concordance rates are higher among monozygotic twins, but range from 50% to 60%, suggesting the contribution of environmental factors to the development of asthma (Koppelman et al., 1999). In addition, the predictive value of a positive family history on the development of childhood asthma only ranges from 11% to 37% (Burke et al., 2003). These findings illustrate that the inheritance pattern is more complex than the Mendelian pattern seen in monogenic disorders.

Modern advances in the field of molecular genetics offer new strategies for finding susceptibility genes associated with asthma pathogenesis. Genome-wide linkage studies and candidate-gene association studies have largely been replaced by genome-wide association studies (GWAS) over the last decade. GWASs provide an affordable and unbiased approach to identify genetic factors underlying complex diseases in large populations. GWASs scan the genome of patients with and without asthma for genetic variations called single nucleotide polymorphisms (SNPs). A polymorphism that occurs more frequently among patients with asthma suggests the genetic variant is involved in the pathogenesis of asthma. However, the GWAS approach requires a high threshold for statistical significance to limit the large number of false positive signals (Visscher et al., 2017). The GABRIEL Consortium in Europe and EVE Consortium in the United States are two of the most important GWASs on asthma. Both studies identified multiple asthma-susceptibility genes with functional roles in cellular inflammation and airway remodeling.

The GABRIEL Consortium analyzed 582,892 SNPs using data from 10,365 participants with asthma and 16,110 healthy controls (Moffatt et al., 2010). The EVE Consortium analyzed a more ethnically diverse group of participants with asthma in the United States (Torgerson et al., 2011). The strongest association with childhood-onset asthma was seen in the *ORMDL3/GSDMB* locus on chromosome 17q21. The role of *ORMDL3* in asthma development is unclear. Recent mouse studies suggest *ORMDL3* expression regulates sphingolipid synthesis. Sphingolipids, such as ceramide, are implicated in the inflammatory response and airway hyperreactivity underlying asthma (James et al., 2019). Both studies identified *IL-33* and *IL1RL1* as asthma-susceptibility genes. Interleukin-33 (IL-33) is a cytokine released in response to airway epithelium damage. The receptor for IL-33 is interleukin 1 receptor-like 1 (IL1RL1 or ST2) which is located on T helper 2 (Th2) cells and group 2 innate lymphoid cells (ILC2). IL-33 activation

of Th2 and ILC2 cells promotes the production of type 2 inflammatory cytokines responsible for allergic asthma (Chan et al., 2019). The EVE Consortium also identified thymic stromal lymphopoietin (TSLP) as a susceptibility locus. TSLP released by airway epithelial cells contributes to allergic asthma by activating ILC2 cells and promoting Th2 cell polarization (Cianferoni and Spergel, 2014). TSLP is the target of emerging biologic therapies because expression is increased in the airway epithelium of patients with asthma (Corren et al., 2017). Interleukin-13 (IL-13) is an example of a type 2 inflammatory cytokine produced by both Th2 and ILC2 cells. IL-13 contributes to asthma pathogenesis by promoting B cell class switching to produce immunoglobulin E (IgE) and mucus secretion from airway epithelial cells. IL-13 is located on chromosome 5q31, a region that contains multiple candidate genes linked to asthma development. The role of IL-13 is highlighted by the improvement in asthma control observed with the use of biologic medications that block IL-4R α and subsequent signaling through the IL-4 and IL-13 receptors.

GWAS and positional cloning also identified susceptibility genes involved in tissue repair and remodeling, including *ADAM33* and *SMAD3* (Van Eerdewegh et al., 2002). *ADAM33* is a metalloprotease present in airway smooth muscle and fibroblasts. The distribution of *ADAM33* and fact that its expression is increased in patients with asthma suggests a role in airway remodeling (Li et al., 2019). *SMAD3* is a key transcription factor for TGF β signaling. TGF β is implicated in cellular inflammation and airway remodeling by promoting differentiation of T helper 17 (Th17) cells and regulating fibrosis, respectively. Recent epigenetic studies show that methylation of *SMAD3* is associated with an increased risk of childhood asthma in infants born to mothers with asthma (DeVries et al., 2017). This is an example of how environmental risk factors can induce changes to DNA, such as acetylation and methylation. Epigenetic modifications can alter asthma susceptibility gene expression and may explain the complex interaction of genetic factors and environmental risk factors (Potaczek et al., 2017). Examples of early life risk factors include exposure to environmental allergens, lifestyle choices, and exposure to disease states and medications, among others. For example, in utero exposure to maternal smoking leads to DNA methylation and maternal smoking is associated with an increased risk of asthma development (Breton et al., 2014; Tinuoye et al., 2013).

The generalizability of the genetic findings for asthma is limited by the lack of ethnic diversity in genetic studies. The majority of GWASs on asthma have been performed on people of European descent even though asthma disproportionately affects ethnic minorities in the US (Burchard et al., 2015; Akinbami et al., 2016). The inclusion of a more ethnically diverse population in the EVE Consortium showed that certain asthma-susceptibility loci may be ancestry specific. The association of *ORMDL3/GSDMB*, *IL-33*, *IL1RL1*, and *TSLP* with asthma was replicated across different ethnic groups; however, *PYHIN1* was identified as a novel susceptibility locus in subjects with African ancestry (Torgerson et al., 2011). Several studies have identified inconsistent association signals between SNPs and asthma susceptibility among different ethnic groups. For example, SNPs in *ORMDL3* that are associated with asthma in European subjects were not detected in African American subjects (Sleiman et al., 2008). The genetic heterogeneity of asthma is best illustrated by the Consortium on Asthma among African-ancestry Populations in the Americas (CAAPA), a GWAS of 7009 participants with asthma and 7645 healthy controls of African ancestry. The CAAPA study replicated multiple loci previously reported in predominantly European populations (e.g. chromosome 17q21) and identified two novel susceptibility loci in 8p23 and 8q24 among subjects with African ancestry. Genetic heterogeneity not only exists between ethnic groups but may also exist among individuals with similar ancestry. For example, the magnitude of association between SNPs in chromosome 17q and asthma risk among African populations was directly proportional to the degree of European ancestry (Daya et al., 2019).

Environmental risk factors

The risk of developing asthma likely depends on the influence of multiple environmental risk factors rather than one modifiable risk factor (Burbank et al., 2017). It has been proposed that environmental risk factors increase the likelihood of asthma in genetically susceptible individuals by altering the development of the respiratory tract and the immune system (Martino and Prescott, 2013). Identification of the most impactful risk factors of asthma contributes to the development of primary prevention strategies and deepens our understanding of asthma pathogenesis (Abreo et al., 2018). Primary prevention strategies aim to prevent the development of asthma in susceptible individuals (Brunwasser and Hartert, 2019). For example, the Canadian Asthma Primary Prevention Study (CAPPS) showed that multiple early life interventions (e.g. dust mite control, pet avoidance, tobacco smoke avoidance, breastfeeding) could reduce asthma prevalence by 7 years of age (Chan-Yeung et al., 2005). The remainder of this section will review the impact of several early life influences on childhood asthma development.

Microbial exposure

The human microbiome is a collection of microorganisms located in the skin, respiratory tract, and gastrointestinal tract (Lynch and Pedersen, 2016). Commensal bacteria have a symbiotic relationship with humans and contribute to the development of the immune system. Germ-free mouse models lacking a gut microbiome have significant defects in immune system maturation and function that contribute to allergic disease (Cahenzli et al., 2013). Environmental factors such as mode of delivery, maternal and infant antibiotic use, and dietary changes can induce dysbiosis, or an alteration in the composition of commensal bacteria (Feehley et al., 2012). The “hygiene hypothesis” illustrates the clinical importance of dysbiosis, and postulates that early life contact to a microbe rich environment confers allergen tolerance and protection from the development of asthma (Arrieta et al., 2015). Early observational studies after German reunification showed that the prevalence of asthma was higher among children in well-developed West Germany than more polluted East Germany (von Mutius et al., 1994). It was subsequently shown that

decreased diversity of the gut microbiome in early infancy was associated with an increased risk of asthma in school-aged children (Abrahamsson et al., 2014). The gut microbiome of children with allergic disease contains a greater abundance of *Bacteroidaceae*, *Clostridiaceae*, and *Enterobacteriaceae* with a lower abundance of *Bifidobacteriaceae* and *Lactobacillaceae* (Zimmermann et al., 2019). Early life changes to the respiratory microbiome are also suspected to contribute to asthma susceptibility. Bacterial colonization of the neonatal upper respiratory tract with *Streptococcus pneumoniae*, *Haemophilus influenzae* and/or *Moraxella catarrhalis* is associated with an increased risk of childhood asthma (Bisgaard et al., 2007). The abundance of *Streptococcus* and *Haemophilus influenzae* is increased in the nasopharynx of young children infected with respiratory syncytial virus (RSV), a known risk factor for childhood asthma. The altered nasopharyngeal microbiome is associated with a pro-inflammatory response and more severe clinical outcomes, suggesting a link between dysbiosis and the host immune response (de Steenhuijsen Pijters et al., 2016).

Mode of delivery and antibiotic exposure are two environmental risk factors that can alter the microbiome. The cesarean birth rate increased by 27% between 1965 and 2015, and multiple studies show that cesarean section is associated with an increased risk of developing asthma (Taffel et al., 1987; American College of Obstetricians and Gynecologists and Society for Maternal Fetal Medicine, 2014; Huang et al., 2015). The infant microbiome is shaped by the mode of delivery. Infants delivered by vaginal delivery are colonized by vaginal flora (*Lactobacillus*, *Bacteroides*), while infants delivered by cesarean section are colonized with skin flora (*Staphylococcus*, *Corynebacterium*, *Propionibacterium*) (Dominguez-Bello et al., 2010). Recent studies suggest that the microbiome of infants born via cesarean section can be partially restored by transfer of maternal vaginal flora (Dominguez-Bello et al., 2016); however, there are no randomized controlled trials to assess this approach. A majority of pregnant women and infants in the first year of life receive at least once course of antibiotics. Prenatal and infant antibiotic use are both associated with a dose-dependent increase in the risk of childhood asthma (Turi et al., 2020; Donovan et al., 2020). It is postulated that inappropriate antibiotic use may reduce the diversity of the infant microbiome beginning in utero (Yassour et al., 2016).

The Urban Environment and Childhood Asthma (URECA) study showed that early childhood exposure to house dust samples enriched with diverse bacteria and perennial allergens (e.g. mouse, cockroach, cat) conferred protection from asthma. The findings suggest that human interaction with diverse microbial products augments the host microbiome and induces immune tolerance to environmental allergens (Lynch et al., 2014). The lower prevalence of asthma in farming environments lends further support to the importance of microbial exposure. However, the prevalence of asthma differs among the Amish and Hutterite farming communities. Although both communities have similar genetic ancestry, the Hutterites practice industrialized farming while the Amish practice traditional farming. For example, Amish children grow up on single-family dairy farms with a dependence on horses for daily living. The prevalence of asthma was four times lower among Amish children than Hutterite children. A key difference was higher microbial diversity and endotoxin levels in Amish homes. Mice exposed to Amish house-dust extracts were protected from airway hyperresponsiveness, suggesting that diverse microbial products within the home confer protection from asthma. The protective effect of Amish house-dust is postulated to involve stimulation of the innate inflammatory response (Stein et al., 2016).

Acute respiratory infections

Acute respiratory infections (ARI) during infancy are most commonly caused by respiratory syncytial virus (RSV) and human rhinovirus (HRV). HRV often leads to a mild upper respiratory infection while RSV is the primary cause of infant lower respiratory tract infection (LRTI) (Tregoning and Schwarze, 2010). Both viruses induce a pro-inflammatory response; however, RSV causes more significant cytopathic damage to the airway epithelium (Vandini et al., 2019). Numerous studies have shown that early life RSV and HRV lower respiratory tract infections are associated with early childhood wheezing (Regnier and Huels, 2013; Liu et al., 2017). The Tucson Children's Respiratory Study (TCRS) followed 1246 newborns and showed that RSV LRTI in the first 3 years of life is associated with an increased risk for wheezing until 11 years of age (Stein et al., 1999). Two prospective studies supported a potential causal role by showing that the administration of RSV immunoprophylaxis to high-risk infants was associated with a decreased risk of recurrent wheezing (Simoes et al., 2010; Blanken et al., 2013). The Children in the US Childhood Origins of Asthma (COAST) study followed 259 newborns, and showed that HRV LRTI in the first 3 years of life was associated with an increased risk of subsequent asthma at 6 years of age (Jackson et al., 2008). The mechanistic relationship between seasonal HRV infections and viral-induced asthma was illustrated by the Preventative Omalizumab or Step-up Therapy for Severe Fall Exacerbations (PROSE) study. The PROSE study found that omalizumab reduced the duration of seasonal HRV infections and reduced the rate of asthma exacerbations in the fall by enhancing IFN- α responses to HRV (Esquivel et al., 2017). It remains unclear whether prevention of respiratory illness can significantly reduce the risk of developing asthma. There are multiple candidate RSV vaccines in ongoing clinical trials to determine if active immunization of infants and/or pregnant women can prevent RSV infection (Mazur et al., 2015). The development of immunization strategies against HRV is limited by lack of cross-protective immunity between numerous HRV serotypes (McLean, 2014).

Allergen exposure

Sensitization to perennial aeroallergens in early childhood is associated with an increased risk of developing asthma (Illi et al., 2006). Perennial allergens include house dust mites, furry animals, mice, cockroach, and fungi. House dust mites are found in mattresses, carpet, and upholstered furniture in humid environments. As many as 50% of children with asthma exhibit sensitization to house dust mite (Ulrik and Backer, 1999). Exposure to the dominant house dust mite allergen Der p 1 in early childhood has been shown to be an important risk factor for childhood asthma (Sporik et al., 1990). Mechanistically, house dust mite allergens

have been shown to activate toll-like receptor 4 on airway epithelial cells to promote a type 2 inflammatory response. House dust mite control as part of two multifaceted intervention trials was associated with a decreased prevalence of asthma (Chan-Yeung et al., 2005; Arshad et al., 2007). Fungi can be found inside and outside the home. *Cladosporium*, *Aspergillus*, and *Penicillium* are indoor fungi that are commonly found in the homes of patients with asthma (Sharpe et al., 2015). Indoor dampness contributes to the growth of certain indoor fungi, and a systemic review found that both indoor dampness and indoor mold are predictors of asthma development (Quansah et al., 2012). Cockroaches and mice are commonly found in inner-city and urban settings. Children exposed to progressively higher concentrations of cockroach allergen Bla g 1 in the home were at a higher risk for developing asthma (Litonjua et al., 2001). Allergen exposure is not limited to the home, and primary prevention strategies must consider all potential areas of exposure. The School Inner-City Asthma Study followed 284 school-aged students attending inner-city schools and showed that asthma morbidity is associated with exposure to high mouse allergen levels in schools (Sheehan et al., 2017). The evidence of early life exposure to furry pets on asthma development is contradictory. Several initial studies suggested a protective effect of early dog exposure (Remes et al., 2001; O'Connor et al., 2018). However, a pooled analysis of over 22,000 children showed no effect of early pet ownership on the risk of asthma in school-aged children (Lodrup Carlsen et al., 2012). It is postulated that pet ownership, like a farm, creates a protective microbe rich environment. Additional randomized controlled trials are needed to establish causality of these risk factors and the effectiveness of primary prevention strategies (Van Mason and Portnoy, 2020).

Asthma phenotypes and endotypes

Asthma is best viewed as a heterogeneous group of disorders leading to a chronic inflammatory pulmonary disease. As new therapies become available, each of which targeting a specific point in the immunologic milieu, it becomes increasingly relevant to distinguish specific forms of asthma at the point of care. Asthma phenotypes refer to the spectrum of clinical presentations, while the different underlying mechanistic pathways are termed endotypes. Currently, endotypes are broadly categorized as type 2 (T2)-high (eosinophilic) or T2-low (non-eosinophilic) (Kuruvilla et al., 2019). Understanding of the cell types and cytokines involved in the pathology of asthma, as well as conceptualizing the manner in which the endotype contributes to the phenotype, is of increasing clinical importance. T2-high phenotypes include early-onset allergic asthma, late-onset eosinophilic asthma, and aspirin-exacerbated respiratory disease (AERD) (Kuruvilla et al., 2019). The T2-low classification is associated with phenotypes which include obesity-related, smoking-related, and advanced age-related asthma (Kuruvilla et al., 2019). The categorization of asthma will continue to evolve as scientific knowledge expands.

Immunology of asthma

Based on inflammatory cell counts in induced sputum, asthma can be broadly classified into four cellular subtypes: eosinophilic, neutrophilic, mixed granulocytic, and paucigranulocytic (Tliba and Panettieri, 2019). Eosinophilic asthma describes patients with elevated sputum eosinophils of greater than 3% (Tliba and Panettieri, 2019). Eosinophilic asthma can be either non-allergic or allergic based on the presence or absence of allergic sensitization (Lambrecht and Hammad, 2015). Neutrophilic asthma describes patients with sputum neutrophilia greater than 64% without sputum eosinophilia (Svenningsen and Nair, 2017). Mixed granulocytic asthma describes patients having both elevated neutrophils and eosinophils (Tliba and Panettieri, 2019). Paucigranulocytic asthma characterizes patients without elevated neutrophils (<64%) or eosinophils (<3%) (Svenningsen and Nair, 2017). Each form may present a unique set of challenges in the clinical realm, including unique responses to treatment. For the purposes of describing the immunologic mechanisms of asthma, we will focus primarily on eosinophilic asthma and neutrophilic asthma, where the greatest depth of immunologic understanding currently exists.

Non-allergic eosinophilic asthma

The discovery of innate lymphoid cells (ILCs), previously termed “nuocytes,” “natural helper cells” or “Innate Helper Type 2 cells (Ih2s)” has allowed much deeper insight into asthma pathogenesis (Monticelli et al., 2012). ILCs are non-antigen dependent lymphoid cells. Type 2 innate lymphoid cells (ILC2s) are significant mediators of eosinophilic inflammation (Lambrecht and Hammad, 2015). ILC2 cells are abundant in the lung, among other tissues, and appear to play an integral role in mediating eosinophilic inflammation even in non-atopic patients, owing to their lack of antigen-specific receptors (Mjosberg and Eidsmo, 2014). Recognition of the importance of ILC2s in the pathophysiology of asthma led to the change in terminology from “Th2-high asthma,” which implies that T helper type 2 (Th2) cells are the predominant driver, to “type-2 (T2) asthma” (Kuruvilla et al., 2019). ILCs respond to a group of cytokines termed “alarmins” which are released by the epithelial barrier in response to external insults. These cytokines include thymic stromal lymphopoietin (TSLP), IL-33, and IL-25 (Roan et al., 2019). A summary of prominent cytokines is provided in Table 1.

TSLP is a member of the IL-2 family of cytokines. Epithelial cells are a significant source of TSLP, with the lungs, skin, and gastrointestinal tract being the primary locations of production (Roan et al., 2019). Although some TSLP is produced under homeostatic conditions, expression and release is increased when epithelial cells are stimulated by infection, mechanical injury, inflammatory cytokines, and proteases (Roan et al., 2019). Other cell types, including dendritic cells (DCs), basophils, and mast

Table 1 Prominent cytokines and their respective roles in asthma.

<i>Cytokine</i>	<i>Primary source</i>	<i>Role in asthma</i>
Type 2 Cytokines		
IL-4	Th2 cells T _H cells +/- ILC2s	Principal cytokine which stimulates B cell class switching to IgE. Induces Th2 differentiation. Eotaxin synthesis by airway epithelium. Airway remodeling.
IL-5	Th2 cells ILC2s	Primary cytokine for eosinophil development, activation, and migration. Proliferation of B cells.
IL-13	Th2 cells ILC2s	B cell class switching to IgE. Goblet cell hyperplasia and mucus production. Upregulates iNOS. Eotaxin synthesis by airway epithelium. Airway remodeling: promotes collagen synthesis from fibroblasts and macrophages. Promotes tissue inflammation.
Alarmins		
IL-25	Epithelial cells Th2 cells	Induces Th2 inflammation. Promotes eosinophil survival. Activates ILC2s.
IL-33	Epithelial cells	Enhances Th2 activation. Activates ILC2s and promotes ILC2 egress from bone marrow. Promotes airway remodeling.
TSLP	Epithelial cells	Primes DCs to induce Th2 differentiation. Activates ILC2s.

The primary cell sources of each cytokine are listed. Cytokines may be derived from other cell sources not listed in this table.

cells, can express TSLP (Roan et al., 2019). High levels of TSLP expression have been linked to multiple atopic diseases, including asthma (Ziegler, 2010). TSLP can directly promote Th2 differentiation of naïve T cells, and increased production of IL-5 and IL-13 by Th2 cells (Rochman et al., 2018). In addition, TSLP signaling during the primary CD4 T cell response can program toward greater effector cytokine production in Th2 memory cells (Rochman et al., 2018). Basophils and ILCs have also emerged as important effector cell populations downstream of TSLP (Roan et al., 2019). The TSLP/ILC axis appears to play an important role in steroid-resistant asthma, at least in part by controlling the phosphorylation of STAT5 (Kabata et al., 2013). Evidence suggests that blockade of TSLP or inhibition of STAT5 restores corticosteroid sensitivity. Thus, the TSLP-STAT5 pathway has been a point of investigation in the treatment of corticosteroid-resistant asthma (Kabata et al., 2013).

IL-33 promotes collagen synthesis and airway remodeling, and has been associated with increased reticular basement membrane thickness on endobronchial biopsies from children with steroid resistant asthma (Sagiani et al., 2013). When evaluating children with steroid resistant asthma via endobronchial biopsy, Sagiani et al. documented similar numbers of IL-13+ cells in the airway of patients and controls. However, IL-33+ cell numbers were significantly increased in the submucosa of asthmatic patients (Sagiani et al., 2013). Following steroid treatment, IL-33 levels were maintained, while IL-13 levels were reduced, in the airway of house dust mite-exposed mice (Sagiani et al., 2013). Even in the absence of CD4+ T cells, asthma may develop through innate mechanisms involving IL-33, natural helper cells, and natural killer T (NKT) cells (Kim et al., 2012; Barlow et al., 2012).

IL-25 is a member of the IL-17 cytokine family (Hong et al., 2020). Unlike other members of the IL-17 family which lead to Th1 inflammation, IL-25 induces Th2 inflammation and production of IL-4, IL-5, and IL-13 (Hong et al., 2020). IL-25 uses both innate (ILC2) and adaptive (Th2 cell) pathways (Hong et al., 2020). A wide variety of cells can secrete IL-25, including but not limited to airway epithelial cells, Th2 cells, eosinophils, basophils, and alveolar macrophages (Hong et al., 2020). IL-25 leads to the polarization of memory Th2 cells (Hong et al., 2020). IL-25-treated eosinophils demonstrate enhanced viability, suggesting that IL-25 delays apoptosis and sustains eosinophilia in the airway (Cheung et al., 2006). ICAM-1 expression on the cell surface of eosinophils, which is essential for recruitment and transendothelial migration of the cells, is also increased by IL-25 (Cheung et al., 2006).

Allergic eosinophilic asthma

Asthma has traditionally been viewed as a purely atopic/eosinophilic disorder mediated by Th2 cells with overproduction of associated cytokines IL-4, IL-5, and IL-13. IgE-mediated sensitization to airborne allergens is the main driver of the pathology in this phenotype. Sensitized Th2 cells produce IL-4, IL-5 and IL-13 upon contact with their antigen (allergen) presented by antigen presenting cells such as DCs (Jonckheere et al., 2019). Allergens directly trigger alarmin release from epithelial cells in a non-IgE mediated manner. Therefore, ILC2 cells also play an active role in producing type 2 cytokines in patients with allergic eosinophilic asthma (Jonckheere et al., 2019). ILC2s are rapidly increased and activated in the asthmatic airway in response to allergen and are potent producers of IL-5 and IL-13 in response to allergen challenge (Chen et al., 2017; Kuruvilla et al., 2019).

There is significant overlap in the roles of IL-4 and IL-13, due in part to the fact that the IL-4 receptor alpha unit is shared by both the IL-4 receptor and the IL-13 receptor. Among the type 2 cytokines, IL-4 is the primary driver of B cell class switching to IgE (Jonckheere et al., 2019). IL-4 is also a major inducer of differentiation of Th2 cells, leading to production of their associated cytokines (Moran and Pavord, 2020). Both IL-4 and IL-13 lead to activation of eotaxin synthesis by airway epithelium, leading to increased airway eosinophilia (Moran and Pavord, 2020). Both cytokines play a role in airway remodeling. IL-4 is known to upregulate fibronectin and collagen synthesis (Moran and Pavord, 2020). IL-13 induces smooth muscle cell proliferation, collagen deposition, and fibroblast transformation and is a major player in remodeling (Moran and Pavord, 2020). IL-13 also enhances goblet cell hyperplasia and mucus production (Moran and Pavord, 2020). IL-13 upregulates inducible nitric oxide synthase (iNOS) in airway epithelial cells (Chibana et al., 2008). This allows for increased production of exhaled nitric oxide (FeNO) which can be used as a biomarker in asthma management (Chibana et al., 2008). The role of IL-13 in lung remodeling is also discussed in the Structural Changes section.

IL-5 is a major factor in eosinophilic inflammation. It is responsible for eosinophil development, activation, and migration. IL-5 promotes eosinophil differentiation from hematopoietic progenitor cells in both the bone marrow and the bronchial mucosa (Pelaia et al., 2019).

Neutrophilic asthma

Clinically, neutrophilic asthma is associated with increased clinical severity of asthma, airway remodeling with irreversible obstruction, and poor response to glucocorticoid therapy (Chang et al., 2017). Neutrophilic asthma is dominated by a mixed Th1 and Th17 cytokine milieu (Lambrecht and Hammad, 2015; Chang et al., 2017). IL-17 contributes to remodeling by promoting fibroblast proliferation, counteracting the anti-inflammatory role of Treg cells, and causing direct contraction of bronchial smooth muscle (Lambrecht and Hammad, 2015). Th17 cells and IL-17 + ILCs (commonly termed ILC3s) demonstrate steroid resistance (Nagakumar et al., 2019). In fact, in vitro assays demonstrate that IL-17 + ILCs are induced by budesonide (Nagakumar et al., 2019). ILC2s and ILC3s have also been implicated in obesity-induced asthma, a specific neutrophilic subtype which is known to be associated with corticosteroid resistance (Everaere et al., 2016).

Structural changes

Airway tissue remodeling resulting from chronic inflammation is characteristic of asthma, including a thickened subepithelial layer often accompanied by fibrosis, smooth muscle hyperplasia, enhanced vascularity, and increased collagen deposition (Banno et al., 2020). Hence, severe asthmatics show abnormal computed tomography (CT) findings including thicker airway walls with narrower lumen and potentially focal bronchial stenoses (Kim et al., 2018). Subepithelial fibrosis is predominantly mediated by submucosal fibroblasts that differentiate into myofibroblasts under the influence of TGF- β (Hough et al., 2020). Increased vascularity also contributes to thickening of the airway walls. New blood vessels generated during asthma-induced angiogenesis may have increased permeability, leading to airway edema (Banno et al., 2020). Tissue remodeling is an inherent part of asthma pathophysiology, as it is directly mediated by the same cytokines that drive the immune response. IL-4, IL-5, and IL-13 have all been shown to drive goblet cell hyperplasia and airway collagen deposition in mice (Banno et al., 2020). IL-13 is perhaps one of the biggest players in tissue remodeling. Mouse models have demonstrated that IL-9's effects on airway remodeling is dependent on IL-13. IL-9 is produced by a T-helper subset termed Th9 lymphocytes (Seumois et al., 2020) as well as ILC2s (Verma et al., 2018). In murine asthma models, IL-9 promotes bronchial hyperresponsiveness, mucus cell metaplasia, is a potent stimulator of mast cells, and plays a significant role in airway remodeling (Lambrecht et al., 2019; Kearley et al., 2011). In addition, IL-13 promotes TGF- β , the powerful mediator of airway fibrosis (Banno et al., 2020). A significant role of TGF- β is that it promotes metalloproteinase-9 (MMP-9) production (Hough et al., 2020). MMP-9, also known as gelatinase-B, alters the extracellular matrix and drives structural changes in the asthmatic airway (Hough et al., 2020). STAT-6, which is downstream of the signaling cascade induced by IL-13, mediates mucus production and promotes subepithelial fibrosis (Banno et al., 2020). Production of periostin in bronchial epithelial cells is upregulated by IL-13 and IL-4 (Izuhara et al., 2016). Periostin is a matricellular protein with participates in modulating the expression of several products such as collagen, chemokines, and TGF- β and plays a role in the extracellular matrix and airway remodeling (Izuhara et al., 2016). While Th2 driven chronic inflammation is a major driver, it does not account for the entire process of airway remodeling in asthma. Characteristics of airway remodeling have been documented in individuals with both allergic and non-allergic asthma (Banno et al., 2020).

Conclusion

Asthma is a complex disease driven by the interaction of genetic factors and early life environmental risk factors. The main features of asthma include airway inflammation leading to bronchial hyperresponsiveness and variable airflow limitation. The prevalence of asthma has increased over time, and disproportionately impacts ethnic minorities and people of low socioeconomic status. There are numerous early life influences associated with the development of asthma, including microbial exposure, acute respiratory infections, and allergen exposure. Multiple asthma phenotypes and endotypes have been identified based on different pathologic

mechanisms, including non-allergic eosinophilic asthma, allergic eosinophilic asthma, and neutrophilic asthma. Airway inflammation is driven by various cytokines, chemokines, and inflammatory cells, and associated with structural changes of the epithelium, basement membrane, and smooth muscle. Knowledge of asthma pathogenesis contributes to the understanding of the diagnostic and therapeutic modalities discussed in the next chapter.

Introduction

Asthma is a common, chronic respiratory disease that affects both children and adults worldwide. Initially thought to be one condition, and treated as such, molecular advances have proven it to be a heterogeneous disease with different clinical manifestations and underlying mechanisms. Current treatment options are much more diverse and targeted than previously. This chapter focuses on the diagnosis of asthma, classification into different phenotypes and endotypes, and discussion of the vast array of treatment considerations. These range from traditional medications to more novel, targeted, biologic therapies as well as non-pharmacologic interventions such as environmental modification.

Diagnosis

Diagnosis of asthma includes a history of characteristic symptoms and demonstration of variable expiratory airflow limitation. Ideally the diagnosis should be made at the initial presentation of symptoms, prior to treatment initiation, which could alter the clinical picture.

History

Vital components of the asthma history include symptoms, their pattern, and precipitating/exacerbating factors. Symptoms suggestive of asthma include wheezing, chest tightness, shortness of breath, or cough. These symptoms usually occur variably over time, sometimes with a seasonal component, and can fluctuate in intensity. Many patients experience nocturnal cough or awakening. Specific triggers include environmental allergens (pollen, dust mites, mold, cockroach, animal dander and secretions), irritants such as cigarette smoke, as well as cold air, exercise, laughter, and viral infections. Prolonged cough after viral infections can also be a clue to the diagnosis of asthma (Reddel et al., 2019).

Spirometry

Spirometry is a physiological test that measures the maximal volume of air that an individual can inspire and expire with maximal effort (Graham et al., 2019). This maneuver measures expiratory airflow limitation or obstruction and is a vital part of the diagnosis of asthma. If the history is suggestive of asthma, patients should undergo spirometry with bronchodilator challenge to assess for reversibility. A reduced FEV₁ with low FEV₁/FVC ratio is indicative of airflow obstruction and bronchodilator reversibility confirms the diagnosis of asthma.

Bronchodilator reversibility refers to an increase in FEV₁ % predicted of more than 12% and >200 mL in adults (in children, an increase from baseline of >12% predicted) 10–15 min after administration of a short-acting β_2 agonist (SABA). Importantly, reversibility is more likely to be present when no SABA has been taken for ≥ 4 h and no long-acting beta agonist taken for ≥ 15 h.

Bronchoprovocation testing

In patients with a history suggestive of asthma but with normal spirometry or absent bronchodilator reversibility, several bronchoprovocation tests can be used to document airway hyperresponsiveness.

Direct challenge tests are highly sensitive and thus are most useful in excluding a diagnosis of asthma. Methacholine is an example of a direct airway bronchoconstrictor and the methacholine challenge test (MCT) is the most widely used direct challenge. During the MCT, a decrease in FEV₁ by 20% with a provocative concentration (PC₂₀) of methacholine <4 mg/dL confirms airway hyperresponsiveness (Coates et al., 2017).

Indirect bronchial stimuli include exercise, hypertonic saline, mannitol, and eucapnic hyperventilation. The most commonly used among these is the exercise test. During an exercise challenge test, a patient must reach a HR >180 for the last 3 min of an 8 min test. A decrease in FEV₁ of >10% predicted value and >200 mL in adults, or >12% predicted in children constitutes a positive exercise test (Reddel et al., 2019).

Phenotypes/endotypes

Historically asthma has been considered to be one disease and a common treatment approach used for nearly all patients. However, over time, the entity of asthma has been increasingly recognized as a heterogeneous condition with a variety of clinical presentations. The term phenotype has been used to describe clinically observable features of a disease without respect to underlying pathophysiology. Such phenotypes include atopic/allergic asthma, late-onset asthma, aspirin-exacerbated respiratory disease (AERD), non-atopic asthma, obesity-associated asthma and asthma of the elderly (Kuruvilla et al., 2019).

More recently, molecular advances have enabled physicians to pair a molecular basis, or an endotype, with a corresponding phenotype. Asthma endotypes describe distinct underlying pathophysiologic mechanisms at a cellular and molecular level thereby facilitating precision medicine. With the advent of biologic medications, endotyping is becoming increasingly important in order to provide the most targeted treatment for patients.

Phenotypes

Phenotypes have traditionally been divided into atopic and non-atopic asthma though other clinical phenotypes have been described based on disease severity, triggers, age at onset, inflammatory patterns and airflow obstruction.

A more modern approach to phenotyping involves the use of cluster analyses in an effort to describe phenotypes in an unbiased manner. Cluster analyses group together asthmatics using algorithms that integrate multiple components. Examples of these cluster analyses include the Severe Asthma Research Program (SARP study) (Moore et al., 2010), sponsored by the NHLBI, Unbiased Biomarkers for the Prediction of Respiratory Disease Outcomes (U-BIOPRED), a European consortium of asthmatics, and Airways Disease Endotyping for Personalized Therapeutics (ADEPT). The consensus among these three consortiums is that two main clusters have emerged—T2 high and T2 low (or non-T2). Of note, the terms Th2 high and Th2 low are also referenced in the asthma literature; however, as innate lymphoid cells have been recognized as part of the inflammatory cascade in asthma, the broader terms T2 high and T2 low have emerged.

Another important finding from these cluster analyses is that eosinophils were present in patients both with and without atopic disease suggesting that patients can have eosinophilic, or T2 inflammation, in the absence of atopy. Some T2 high patients are steroid responsive and others are steroid resistant, further reinforcing the need for precision medicine with biologics.

Endotypes

In 2008, the term endotype developed as a means of describing a molecular basis, or mechanism, underlying a specific phenotype. As targeted therapeutics have become increasingly available, establishment of biomarkers is even more important to characterize a patient's asthma as specifically as possible (Table 1).

Table 1 Endotypes and phenotypes of asthma in adults and children.

Endotype	Phenotype	Clinical Characteristics	Molecular Mechanism	Biomarkers	Natural History
T2 High	Atopic (Adult)	Well-defined, early onset, steroid sensitive	Allergic sensitization	Blood/sputum eosinophils, allergen specific IgE, FeNO, total IgE	Identifiable and treatable, preserved lung function
	Atopic (Pediatric)	Uncontrolled symptoms, atopy, frequent exacerbations, steroid sensitive	Allergic sensitization	Blood eosinophils, allergen specific IgE, FeNO, total IgE	Early-onset severe asthma, impaired lung function
	Late-onset	+/- concomitant CRSwNP, steroid refractory	<i>S. aureus</i> enterotoxin	Blood/sputum eosinophil count, FeNO	Severe from onset, frequent exacerbations
	AERD	Adult-onset	Dysregulated arachidonic acid metabolism	Blood/sputum eosinophil count, urinary LTE4	Severe from onset, frequent exacerbations
Non-T2	Non-atopic (Adult)	Paucigranulocytic or neutrophilic	NLRP3/IL-1B, altered miRNA expression, TH17	Induced sputum neutrophils, MMP-9 in BAL	Variable course and lung function
	Non-atopic (Pediatric)	Neutrophilic	IL-17	Serum IL-17, sputum neutrophils, TWEAK ^a	Better lung function than atopic asthma
	Smokers	Older adults	Oxidative stress, mixed Th2 high/Th2 low	Induced sputum neutrophil count	Frequent exacerbations lower lung function
	Obesity-related	Female sex	Oxidative stress, neutrophils, ↑ innate activation	Serum IL-6	Severe symptoms, preserved lung function
	Elderly	>50 to >65 years at onset	Immunosenescence, Th1, Th17 inflammation	Induced sputum neutrophils	Steroid-resistant

^aHuman Tumor Necrosis Factor –like weak inducer of apoptosis: novel biomarker under investigation.

Biomarkers

Historically, bronchoscopy with bronchoalveolar lavage and bronchial brushings have been considered the gold standard for diagnosis of airway inflammation and remodeling, but these procedures are too invasive for routine use. Hence alternative, non-invasive biomarkers are attractive tools.

A biomarker is defined as a characteristic that is objectively measured and evaluated as an indicator of an intervention. In the field of asthma, biomarkers are useful in categorizing patients as either T2 high or T2 low which ultimately establishes candidacy for specific therapies. Biomarkers for T2 high asthma include sputum eosinophils, peripheral eosinophils, total serum IgE, periostin, allergen specific IgE, FeNo, and to a lesser extent, dipeptidyl peptidase 4 (DPP-4), and LTE4. Unfortunately, biomarkers for T2 low asthma are lacking, and this endotype is characterized primarily by either neutrophilic or paucigranulocytic sputum samples.

Peripheral eosinophils

Peripheral eosinophil count is a non-invasive and easy to obtain biomarker for asthma. In both pediatric and adult cohorts, absolute eosinophil counts (AECs) have correlated with the risk of acute exacerbations (Mogensen et al., 2018). In the INFANT study of children ages 12–59 months, the presence of aeroallergen sensitization and an absolute eosinophil count >300 identified children at high risk for exacerbation and predicted good response to daily ICS (Fitzpatrick et al., 2016). In adults as well as children who require a step-up in management to include biologic therapy, peripheral eosinophil count can help guide targeted therapy. One limitation of this biomarker is the inconsistent correlation between sputum and peripheral eosinophilia over time.

Sputum eosinophils

Sputum eosinophils are typically considered the gold standard for diagnosing T2 high asthma in the office and levels >2% are considered positive (Miranda et al., 2004). A recent study found an association between sputum eosinophil counts and asthma control. The authors noted that in patients with uncontrolled asthma who are on ICS therapy, residual sputum eosinophilia suggests opportunity for improvement in asthma control with ICS (Demarche et al., 2017). An unfortunate limitation of sputum eosinophilia is that quality sputum samples are difficult to obtain in regular practice, particularly in children. When obtained in children, however, they correlate directly with airway hyperreactivity and inversely with FEV₁ (Licari et al., 2018).

FeNO

FeNO, or fractional exhaled nitric oxide, is a safe and non-invasive measurement of eosinophilic airway inflammation. This test is a simple, quantitative means of assessing airway inflammation directly, as compared to spirometry which measures inflammation indirectly. Previously, this biomarker was used mostly in research settings, but in the era of biologics, measurement in clinical practice is becoming increasingly important. Values <25 ppb in adults and <20 ppb in children suggest that eosinophilic inflammation and steroid responsiveness are less likely; values >50 ppb in adults, and >35 ppb in children, suggest that eosinophilic inflammation and steroid responsiveness are more likely (Dweik et al., 2011).

A 2018 review of NHANES data from 1419 subjects, ages 6–79 years from 2007 to 2012 found that simultaneous elevation in both FeNO and blood eosinophils correlated with reduced lung function (FEV_1 <80%) and wheezing symptoms in asthmatics (Mogensen et al., 2018).

Total and allergen specific IgE

Total IgE level and allergen specific IgE levels are biomarkers of atopic status. As allergic asthma is the most common phenotype, assessment of allergic sensitization is a critical component in the evaluation of asthmatic patients. In the SARP study group with early-onset asthma 80% of patients were atopic, and among those with late onset eosinophilic asthma, 50% of patients were atopic (Moore et al., 2010). In infants with viral-induced wheeze, elevated total IgE levels predict later asthma development (Lemanske Jr, 2002) and high levels of allergen specific IgE correlate with asthma severity in children (Szeffler et al., 2012).

Periostin

Periostin is an extracellular matrix protein secreted by airway epithelial cells and lung fibroblasts after induction by IL-4 and IL-13 (Takayama et al., 2006). It localizes to the subepithelial region of the airway and plays a role in airway remodeling, subepithelial fibrosis, eosinophil recruitment, and regulation of mucous production from goblet cells. In adults, it may be a useful biomarker due to its upregulation by IL-4 and IL-13. Its role in the pediatric population is unclear though, as children have inherently higher levels compared to adults, presumably due to rapid bone growth. It may also be elevated in other atopic conditions such as atopic dermatitis and allergic rhinitis which is another potential limitation (Licari et al., 2018).

Urinary LTE4

LTE4 is a byproduct of the cystinyl leukotriene pathway that can be detected in urine samples and serves as biomarker of upregulation of this pathway. It has been observed to be elevated in allergen-induced asthma and in AERD and is helpful in diagnosing aspirin sensitive respiratory disease (Divekar et al., 2016).

Dipeptidyl peptidase 4 (DPP-4)

DPP-4 is a glycoprotein present in cell membranes and as a soluble blood protein. A recent study noted that DPP-4 expression is enhanced in bronchial epithelial cells of asthmatics, particularly in steroid naïve patients. Expression was also upregulated in the presence of IL-13 (Shiobara et al., 2016). Further studies of DPP-4 suggest that it may be another helpful biomarker for asthma (Emson et al., 2018).

After diagnosis of asthma with history and spirometry, and subsequent assessment of phenotype and endotype using the appropriate biomarkers, clinicians can develop a targeted treatment plan.

Treatment and management

Optimal treatment or management of asthma is directed towards reducing impairment from disease symptoms, abating the risks from use of asthma medications and minimizing long term disease sequelae. This requires multifaceted targeting of asthma triggers, avoiding exacerbations, and preventing deterioration. When targeting asthma triggers, comorbid conditions exacerbating asthma as well as environmental factors must be considered. Concurrent active management of common comorbid conditions such as gastroesophageal reflux disease, obstructive sleep apnea, obesity, and vocal cord dysfunction should be done (Boulet, 2014). Avoidance or mitigation of environmental irritants such as cigarette smoke, strong odors, and air pollution. Particulate matter (PM) in different sizes from coarse (2.5–10 μm), fine (0.1–2.5 μm) and ultrafine (<0.1 μm) can deposit in the bronchi, bronchioles and cellular structures directly, respectively (Wu et al., 2018).

Avoidance of allergic triggers for the patient such as pet dander, mold, or other aeroallergens, is also an important aspect of targeting triggers. Specific subcutaneous and sublingual aeroallergen immunotherapy (AIT) is a disease modifying process that amends the immunological milieu towards tolerance to aeroallergen, inducing allergen specific regulatory T cells, regulatory B cells, and innate lymphoid cells (ILCs), which lead to increased IL-10, and TGF- β . Clinically, this has been shown to prevent the development of asthma and improve control. Several studies have shown the disease modifying effects of AIT on allergic asthma, including several studies which show an improvement in symptom scores and medication use (Alvaro-Lozano et al., 2020).

Table 2 Stepwise approach to asthma controller medication management categorized by age (bold-preferred).

Age	Mild intermittent or Step 1 (and rescue)	Mild Persistent ^a or Step 2/3	Moderate Persistent ^a or Step 3/4 ^d	Severe Persistent ^a or Step 4/5 ^d	Alternative Add on ^b
Children 0–4 years	SABA as needed	Low dose ICS ^c	Low dose ICS + LTRA ^c	Medium dose ICS ^c - Medium dose ICS + LABA ^c or - Medium dose ICS + LTRA ^c	Cromolyn LTRA
Children 5–11 years	SABA as needed	Low dose ICS ^c	Medium dose ICS ^c - Medium dose ICS + LTRA ^c or - Medium dose ICS + LABA ^c	High dose ICS ^c - High dose ICS + LABA ^c or - High dose ICS + LTRA ^c	Cromolyn LTRA Nedocromil Theophylline Biologic
Children ≥ 12 years, and Adults	ICS + LABA as needed - SABA as needed	Low dose ICS ^e	Low dose ICS + LABA ^e - Medium dose – ICS ^e or - Medium dose ICS + LTRA ^e or - Medium dose ICS + LABA ^e	Medium/High dose ICS + LABA ^e - High dose ICS ^e or - High dose ICS + LTRA ^e	Cromolyn LTRA Nedocromil Theophylline Tiotropium Biologic

SABA, short acting beta agonist; LABA, long acting beta agonist; ICS, Inhaled Corticosteroid; LTRA, Leukotriene Receptor Antagonist.

^aDaily medications.

^bThese medications are used as add on therapy to a maintenance regimen treatment for asthma; If needed, oral corticosteroids can be used but can be associated with significant side effects if used long term.

^cRescue: SABA.

^dReferral to asthma specialist

^eRescue: ICS + LABA.

Optimal management of asthma also requires routine monitoring of asthma symptoms, and tailoring the short- and long-term treatment regimen in response. The process starts with a baseline assessment of asthma severity, history of control/exacerbations, current control, triggers, exposures to triggers, and personal goals for the particular patient. Then, after implementation of a treatment plan, re-assessment must continue, followed by adjustment of treatment plan for achievement of personal goals. This monitoring and modification process should continue long term. Traditionally, the medications used to treat asthma are separated into immediate response medications (*rescue*), long-term or preventative medications (*controller*) and *add on therapies*. Add-on treatments are often used for severe asthma or if controller medications have not fully achieved the patient's personal goals.

The management of asthma with medications is categorized based on the age of the patient, with categories of infant and children age 0–4 years, children 5–12, and adolescents and adults. A stepwise approach in escalating the number and type of medications as needed after assessing response, is recommended. Table 2 provides a brief overview of these recommendations, and the individual medications are discussed below. Although many guidelines have gone away from rigid classifications of asthma as mild, moderate and severe, these are used as loose methods of classification at baseline, followed by reassessment after initial implementation of a treatment plan.

Immediate response medications (*Rescue*)

β_2 Agonists

β_2 Agonists bind to the β_2 adrenergic receptor on airway smooth muscle, leading to activation of adenylate cyclase and a signaling cascade that results in relaxation of airway smooth muscles. Early β_2 agonists included albuterol, terbutaline, and fenoterol, each with a short duration of action (Cazzola et al., 2013). Short acting β_2 agonists (SABA), or bronchodilators, were the immediate response medications of choice for acute asthma symptoms such as shortness of breath or wheezing, and are typically used to relieve bronchospasm within minutes of use, peaking at 1 h after use, with a duration of action of 4–6 h (FDA, 2008). Numerous initial studies have established their efficacy and routine clinical practice support their use (Horak et al., 2016). Many different formulations exist. However, recent Global Initiative for Asthma (GINA) guidelines prefer the use of long acting bronchodilators (LABA) in combination with an inhaled corticosteroid (ICS) as the immediate response medication of choice for the relief of acute bronchospasm in adolescents and adults with asthma, and the use of SABA was considered the alternative option. For children under the age of 11 years, SABA are still the first line option for relief of acute symptoms (GINA Guidelines, 2020). Minimizing the use of SABA or rescue ICS + LABA is an important goal of asthma management.

Anticholinergics

Ipratropium bromide, a short acting muscarinic antagonists (SAMA), was introduced in the market in the 1970s, for use in the relief of obstructive airway disease (Chervinsky, 1977). Since its introduction, several studies have examined the efficacy of SAMA such as ipratropium bromide in comparison to SABA such as salbutamol. Most of the studies found that SABA had greater bronchodilation

than SAMA with noted difference in forced expiratory volume in the first second (FEV1) up to 6 h post administration to patients with asthma (Novelli et al., 2012). Thus, SAMA are usually not used alone for the treatment of acute symptoms, but have shown efficacy when used in combination with SABA in the acute setting (Durrani and Busse, 2014).

Magnesium sulfate

Magnesium Sulfate (MgSO_4) which is a tocolytic/antiarrhythmic, has been shown to have bronchodilator and mild anti-inflammatory effects in the severe exacerbations. It is for parenteral use and when given in the acute setting for unresponsive asthma, was shown to decrease rates of hospital admission in several studies. However, this remains a controversial area (Camargo Jr and Rowe, 2014).

Systemic corticosteroids

Many evidence based guidelines support the use of oral or intravenous systemic corticosteroids in the acute treatment of uncontrolled asthma. Systemic steroids have a potent anti-inflammatory effect and are a principle treatment of choice for a severe exacerbation that is not responsive to intensive treatment with short acting bronchodilators. The onset of action is thought to occur within an hour to 6 h after administration. The usual dosing is weight dependent in children and 40–60 mg per day in adults; higher doses are sometimes chosen for severe exacerbations (Castillo et al., 2017). However, long term use has a high incidence of adverse effects, including endocrine, immunologic, cardiovascular, gastrointestinal, musculoskeletal, dermatologic and hematologic effects.

Anti-inflammatory medications (Maintenance)

Asthma controller medications are used to decrease airway inflammation, obstruction, prevent exacerbations, and long term to minimize the decline in lung function. Long term goals should be to achieve normal activity including achievement of patient specific personal goals, while minimizing side effects from medications. This requires continual assessment of asthma control, medication effects, patient communication, and personalized management of controller medications.

Inhaled corticosteroids (ICS)

Inhaled corticosteroids are the first line treatment of persistent asthma, regardless of age or severity of asthma (Barnes, 1998). They are the most effective long-term treatment option for asthma and many studies have shown their safety and efficacy in asthma (Ye et al., 2017). Corticosteroids bind to the glucocorticoid receptor complex in the cytoplasm, which attaches to the glucocorticoid response element that promotes the production of anti-inflammatory proteins and inhibits pro-inflammatory proteins. Inhaled corticosteroids have been shown to not only decrease airway inflammation, but also to decrease bronchial hyper responsiveness by several fold, decrease asthma exacerbation frequency and severity, increase lung function, improve quality of life and be beneficial in decreasing hospitalizations as well as asthma mortality (Fanta, 2009).

This class of medications also block the late phase allergen induced reactions but do not change the underlying severity of the disease or its progression. The use of these medications also should be weighed against the small risks of local or systemic adverse effects such as oral candidiasis, or growth effects in children. A step-up approach is recommended to limit exposure to the lowest amounts to achieve therapeutic control of symptoms. This can clinically require consideration of many factors that include the potency of a specific ICS, patient age, type of delivery device used, insurance coverage/cost, prior response to the medication, systemic absorption rate, and taste, to name a few (Jackson et al., 2014). There are many ICS products on the market and they all target the inflammatory cascade. Overall, they have much fewer adverse effects in comparison to oral corticosteroids, although due to expected long term use of these medications, risk, benefits and alternatives must always be considered in making treatment decisions. However, given the long standing favorable safety profile, clear evidence of efficacy, manageable costs, and wide availability, ICS class of medications are the mainstay of the long term maintenance management of asthma in asthma guidelines.

Long acting bronchodilators

Similar to SABA, long acting beta agonists (LABA) improve airway airflow obstruction by bronchodilatory effects but last for at least 12 h in comparison. They only recommended for use in combination with an ICS for long term preventative use in children with asthma but may also be used for both maintenance control of asthma when ICS alone has failed, or for rescue at times of uncontrolled symptoms, in adolescents and adults (GINA Guidelines, 2020). The most common medications of this class that are on the market are Salmeterol and Formoterol.

Long acting anticholinergics

Long acting anticholinergic medications (LAMA) such as tiotropium bromide were approved for the treatment of chronic obstructive pulmonary disease (COPD) in 2004. Since that time, this class of medication shown to improve symptoms and lung function in asthma when added to ICS for patients with poorly controlled asthma (Peters et al., 2010). Tiotropium has also been approved for add on therapy of poorly controlled severe asthma in children (Radovanovic et al., 2017).

Xanthine derivatives

Methylxanthines in general and theophylline in particular, were used much more commonly in the past due to their bronchodilator activity. However, their routine use has become much more limited due to the risks for systemic toxicity and a narrow therapeutic window of efficacy. Monitoring of serum theophylline levels would be required. Its use is not recommended in children but may be considered for add on therapy in adults and adolescents with poor response to bronchodilators and other first line asthma medications (GINA Guidelines, 2020).

Immunological modulation using biologic therapies

Asthma phenotypes and endotype have helped characterize observable, and laboratory features of the disease for a more targeted approach to management and treatment of the disease. As such, the presence or absence of T_H2 type inflammation including T_H2 cytokines, IL-4, 5 and 13 as well as allergen specific IgE, or peripheral eosinophilia is known to identify subsets of asthma patients who have higher response rates to biologic therapies. Treatment with the commercially available monoclonal antibodies is typically reserved for patients with severe asthma and with a phenotype or biomarker profile suggestive of higher likelihood of response. The risks, benefits and alternatives of treatment with biologics must always be considered.

Köhler and Milstein first developed the method for immortalization of B cells for the purpose of antibody production in 1970. Primary animal lymphocytes were fused onto immortalized lymphoblastoid or myeloma cells, and the fused cells were isolated using hybridoma technology. However, initial efforts were limited by human anti-mouse antibodies (HAMA), and soon led to the “humanization” of the monoclonal antibodies by substituting a human constant region. However, the large-scale production of monoclonal antibodies (mAb) for human therapy soon evolved to include recombinant DNA technology expressed in a mammalian host cell such as in cultured Chinese Hamster Ovary (CHO) cells or murine myeloma non-secreting cells (NSO) (Kunert and Reinhart, 2016).

Currently, there are five FDA approved monoclonal antibodies for the treatment of asthma. These are Omalizumab, Mepolizumab, Reslizumab, Dupilumab, and Benralizumab. These products are typically used in older children and adults, with persistent asthma, poorly controlled on inhaled corticosteroids, and may be considered in situations where the use of conventional asthma treatments is contraindicated. Table 3 lists the details of each of these treatments, including the indications for use, mechanism of action, dates of approval, source, and age of approved use. Fig. 1 shows the target sites for each of the currently approved mAb.

Each of these products targets the inflammatory cascade at different points, and the success of treatment is dependent on choosing the right product for the patient. Recent studies have compared the response rate of biologics in correlation with exacerbation rates prior to commencement of the biologic and on baseline serum eosinophilia. The clinical trial results have been most favorable in improving rates of asthma exacerbation for dupilumab, mepolizumab, and reslizumab. Clinical trials for benralizumab and dupilumab have shown a steroid sparing effect, and an improvement in lung function. (Doroudchi et al., 2020) Therefore, depending on the goal for a patient, their biomarker and phenotype, the appropriate biologic treatment can be initiated.

Table 3 Currently available biologic treatments for asthma.

Medication	Brand Name	Mechanism	Source	Dosage	Age approved for	Required	Comorbid conditions treated	Year of US approval
Omalizumab	Xolair	Anti IgE receptor antibody	Humanized (mouse), CHO	Subcutaneous injection every 2–4 weeks	≥ 6 years	IgE in range, +IgE (skin or serum) to perennial aeroallergen, failed ICS	Chronic Urticaria	2003
Mepolizumab	Nucala	Anti-IL-5 antibody	Humanized (mouse), CHO	Subcutaneous injection, every 4 weeks	≥ 6 years	Eosinophilic Asthma	Eosinophilic granulomatosis with polyangiitis (EGPA)	2015
Reslizumab	Cinqair	Anti-IL-5 antibody	Humanized (rat), NSO	Intravenous infusion, every 4 weeks	≥ 18 years	Severe, eosinophilic asthma		2016
Dupilumab	Dupixent	Anti-IL-4 receptor alpha chain antibody	Human IgG4 antibody, CHO	Subcutaneous every 2–4 weeks	≥ 12 years	Moderate to severe eosinophilic asthma, or oral corticosteroid dependent asthma	Atopic Dermatitis, Chronic Rhinosinusitis with nasal polyposis	2017
Benralizumab	Fasenra	Anti-IL-5 receptor antibody	Humanized (mouse), CHO	Subcutaneous injection every 4 weeks for first 3 doses, then every 8 weeks	≥ 12 years	Severe, eosinophilic asthma		2017

Fig. 1 Mechanisms for currently approved asthma biologics. From Doroudchi A Pathria M and Modena BD (2020) Asthma biologics: Comparing trial designs, patient cohorts and study results. *Annals of Allergy Asthma and Immunology* 124: 44–56.

Conclusion

To summarize, asthma is a multifactorial chronic disease with a wide spectrum of severity, which requires a personalized approach to diagnosis, classification, and management. Clinicians must not only accurately diagnose asthma from a large differential of asthma mimickers, but they must also consider the phenotype/endotype of asthma in each patient, and follow a stepwise approach to management. Concurrently, it is important to address not only the pharmacological treatment, but also the social and environmental triggers of asthma, keeping in mind, the individual patient goals that are specific to patient age and preference. In addition, the side effect profile from pharmacotherapy, cost of treatment, and response to therapy should routinely be reassessed to tailor or adjust the management. New treatment options continue to be developed and the clinician's toolbox must be periodically updated to adapt to evidence based guidelines.

Glossary

Allergen A specific protein capable on initiating the formation of allergen-specific IgE antibodies in susceptible individuals.

Anaphylaxis An allergic response involving multiple organ systems that is often severe.

Basophil Blood cell that contains mediators of allergic reactions.

Celiac disease Malabsorption syndrome apparently caused by cell-mediated immune response to proteins from wheat, rye, barley, and related grains.

Food allergy Illness occurring in some individuals upon ingestion of certain foods that elicit an abnormal immune response in that individual to specific proteins (allergens) from certain foods.

IgE A class of immunoglobulins (antibodies) involved in allergic reactions.

Mast cell Type of cell present in many tissues that contain mediators of allergic reaction.

Introduction

“Quod ali cibus est allis faut acre venenum.” One man’s food is another man’s poison. Although not the original intent, this very old quote from Lucretius, a Roman philosopher, defines food allergy. Some individuals in the population experience adverse reactions upon ingestion of foods that are safe and nutritious for the vast majority. These individualistic adverse reactions to foods occur through a variety of mechanisms including food allergies, metabolic food disorders also known as food intolerances, and food sensitivities. The most serious of these illnesses are food allergies. Food allergies affect only a small fraction of the overall population. Food allergies involve an abnormal immunological response to a particular food or food component, usually a naturally occurring protein component of the food. The most common form of food allergy occurs through an antibody-mediated mechanism involving immunoglobulin E or IgE. These allergies are known as immediate hypersensitivity reactions because the symptoms ensue within minutes to a few hours after ingestion of the offending food. However, cell-mediated

food allergies can also occur. These allergies are known as delayed hypersensitivity reactions because the symptoms occur 24–72 h after ingestion of the food. While celiac disease, also known as gluten-sensitive enteropathy, is not often identified as a form of food allergy, it is a cell-mediated intestinal inflammatory response.

IgE-mediated food allergy

From a public health perspective, IgE-mediated food allergies are arguably the most important class of food allergy. While the number of affected individuals is modest, the reactions of some affected individuals can be quite severe, even life-threatening, especially if a significant quantity of the offending food is inadvertently ingested. Furthermore, the degree of tolerance for the offending food is small making the implementation of safe and effective avoidance diets more difficult.

Mechanism

The mechanism of IgE-mediated food allergy occurs through two phases: sensitization followed by elicitation (Anvari et al., 2019). Many foods contain one or more proteins that can trigger the formation of IgE antibody development among susceptible individuals, a process known as sensitization. While all humans have IgE antibodies, the majority will not produce IgE antibodies specific to a particular allergen. Even in susceptible individuals, IgE antibodies are typically formed to relatively few proteins. In many cases, exposure to a potentially allergenic food will often result in no immune response, known as oral tolerance. IgE-mediated food allergy can be viewed as a breakdown in oral tolerance (Chinthrajah et al., 2016). Some food proteins are more likely to elicit IgE antibody formation than others. Many factors including the susceptibility of the individual, the immunogenic nature of the food and its constituent proteins, the age of exposure, the route of exposure, and the dose, duration, and frequency of exposure are likely to influence the formation of allergen-specific IgE antibodies. Sensitization can occur from exposure to a food allergen through the gastrointestinal tract or the skin when their barrier functions are compromised (Sicherer and Sampson, 2018). In young infants, exposure to a food by the oral route seems to induce tolerance, while exposure to small amounts of the food through abraded skin in infants with eczema may induce sensitization (du Toit et al., 2018).

The IgE antibodies produced during the sensitization phase are highly specific and will recognize only a specific portion of the food protein that they are directed against. Occasionally, IgE antibodies produced against one particular protein in a specific food will confer sensitivity to another food either because the food is closely related or because it shares a common segment with the allergenic protein.

Allergen-specific IgE antibodies, once produced, attach themselves to the membrane surfaces of two types of specialized effector cells: mast cells that are found in many different tissues and basophils that are found in the blood. In this process, the mast cells and basophils become activated and ready to respond to subsequent exposure to that specific food allergen (the elicitation phase). Adverse reactions will then occur on any subsequent exposure to the specific allergenic protein or some closely related protein. Sensitization to a particular food allergen does not invariably mean that an adverse reaction will occur upon subsequent exposure to that food. It is possible to be sensitized but not reactive to a particular allergen. When reactions occur in the elicitation phase, the food allergen cross-links to IgE antibody molecules on the surface of the mast cell or basophil. This interaction between the allergen and the allergen-specific IgE elicits the release of a host of mediators of allergic disease which are either stored or formed by the mast cells and basophils. Several dozen different mediators have been identified including histamine, prostaglandins, and leukotrienes (Anvari et al., 2019; Valenta et al., 2015). These mediators are responsible for the symptoms associated with allergies through interactions with receptors in various target organs in the body. The interaction of a small amount of allergen with the allergen-specific IgE antibodies results in the immediate release of comparatively large quantities of the various mediators into the bloodstream and tissues. Thus, exposure to extremely small amounts of allergens can elicit symptoms.

While ingestion is the most common route of exposure to an allergenic food, symptoms can be provoked by exposure through the respiratory tract or the skin. Occupational food allergies can occur in food industry workers who are exposed by inhalation or skin contact (Fukutomi, 2019; Jeebhay et al., 2019). However, consumers may also show reactions when respiratory or cutaneous exposures occur. Often symptoms from such exposures are localized as occupational asthma or contact dermatitis or urticaria (hives).

IgE-mediated reactions can also occur from environmental exposures to many other sources of allergens including pollens, mold spores, animal danders, bee venom, and pharmaceuticals. In these cases, the source of the allergen is often environmental and not food-related. Exposure is through the respiratory route typically for pollens, mold spores, and animal danders and by injection for bee venoms.

Symptoms

IgE-mediated food allergies are designated as immediate hypersensitivity reactions because of the short onset time between the ingestion of the offending food and the onset of symptoms. Since the mediators released from the mast cells and basophils can interact with receptors in a number of different tissues in the body, a rather wide variety of symptoms can be associated with IgE-mediated food allergies as shown in Table 1 (Taylor and Baumert, 2020). Most food-allergic individuals experience only a few of the many possible symptoms.

Table 1 Symptoms of IgE-mediated food allergies.

<i>Gastrointestinal symptoms</i>	<i>Cutaneous symptoms</i>
Nausea	Urticaria
Vomiting	Dermatitis or eczema
Diarrhea	Angioedema
Abdominal cramping	Pruritis
<i>Respiratory symptoms</i>	<i>Other symptoms</i>
Rhinitis	Anaphylactic shock
Asthma	Laryngeal edema

Most of the symptoms of IgE-mediated food allergies are not particularly definitive which can make diagnosis rather difficult. For example, the gastrointestinal manifestations of food allergies can also be associated with many other foodborne illnesses and a variety of other diseases as well. Additionally, there are millions of asthmatics, but only a small percentage are allergic to foods.

Anaphylactic shock is, by far, the most serious manifestation of food allergies. Anaphylactic shock involves gastrointestinal, cutaneous, and respiratory symptoms in combination with a dramatic fall in blood pressure and cardiovascular complications. Death can ensue within minutes of the onset of anaphylactic shock. Fortunately, relatively few individuals with food allergies are susceptible to such severe reactions after the ingestion of the offending food.

The severity of an allergic reaction will be dependent to some extent on the amount of the offending food that is ingested. Severe reactions are more likely to occur when an allergic individual inadvertently ingests a large amount of the offending food, especially if that individual happens to be exquisitely sensitive. However, exposure to even trace quantities can elicit noticeable reactions due to the large release of mediators.

Perhaps the most common and possibly the mildest form of IgE-mediated food allergy is the so-called oral allergy syndrome (OAS) associated with the ingestion of various fresh fruits and vegetables (Muluk and Cingi, 2018). OAS symptoms are confined to the oropharyngeal area including pruritis, urticaria, and angioedema. In OAS, sensitization occurs to allergens present in pollens such as birch and ragweed. With OAS, sensitization to the pollen allergens increases the likelihood of sensitization to specific foods. Although fresh fruits and vegetables contain comparatively low quantities of proteins, sufficient exposure occurs to elicit symptoms in the oropharyngeal region. The allergens involved in OAS are quite susceptible to digestive proteases in the gastrointestinal tract, thus systemic reactions to these foods are infrequent. These fruit and vegetable allergens are also heat-labile. Individuals with OAS can often safely consume the heat-processed versions of these foods. In some cases, a more stable allergen called lipid transfer protein has been implicated in allergic reactions to certain fruits and vegetables and these reactions are more likely to be systemic and severe (Asero et al., 2018).

Exercise-induced food allergies are a subset of the immediate hypersensitivity reactions to foods (Foong et al., 2019). In these cases, exercise must be done coincident with ingestion of the food for symptoms to occur. Exercise-induced food allergies have been associated with several foods including shellfish, wheat, and celery. The symptoms of exercise-induced food allergies are individualistic, variable, and similar in nature to those involved in other food allergies. Exercise-induced allergies can also exist without any role for food intake. The mechanism of this illness is not well understood, although the involvement of IgE antibodies is apparent.

Sources

The most common allergenic foods are peanuts, tree nuts (almonds, walnuts, pecans, cashews, etc.), soybeans, cows' milk, eggs, fish, crustacean shellfish (shrimp, crab, lobster, etc.), and wheat (Bjorksten et al., 2008). On a worldwide basis, these eight foods or food groups are thought to be responsible for 90% of all food allergies. Allergies to crustacean shellfish and peanuts are the most common food allergies in the US. Cows' milk allergy is the most common food allergy among infants due to the widespread consumption of milk during the first months of life. Eggs are another commonly allergenic food among infants and young children because of the frequent use of eggs as a weaning food. In the US, peanut allergy is also relatively common among young children because of the popularity of peanut butter. However, in some other countries, peanut butter is less popular and peanut allergy is less prevalent especially in childhood. Thus, the prevalence of any specific type of food allergy is related to some extent to cultural food preferences. For example, in some Asian countries, buckwheat is a common allergenic food because of the popularity of soba noodles leading to frequent exposure to buckwheat (Shek and Lee, 2006). By contrast, buckwheat allergy is not common in the US probably because buckwheat is not frequently eaten in the US. Different regions of the world recognize different foods as commonly allergenic or priority allergens for the purposes of labeling regulations. Milk, eggs, fish, crustacean shellfish, peanut, soybean, tree nuts, and cereal grain sources of gluten (including wheat) are recognized by most countries. Molluscan shellfish (clams, oysters, squid, snails, etc.), mustard, and lupine are considered as priority allergenic foods in Canada and the European Union. Sesame seed is identified as a commonly allergenic food in Canada, the European Union, and Australia/New Zealand. The European Union also recognizes celery as commonly allergenic.

Any food that contains protein has the potential to elicit an allergic reaction in someone. The most common allergenic foods tend to be foods with high protein content that are frequently consumed. The exceptions are beef, pork, chicken, and turkey which are rarely allergenic despite their frequent consumption and high protein content.

Food allergens

The vast majority of the allergens in foods are naturally occurring proteins (Sathe et al., 2016). But foods contain millions of proteins and most do not provoke a sensitizing response. Thus, only a very small percentage of all known food proteins are known to be allergens. Even with the commonly allergenic foods, only a few of the many proteins in those foods are identified as allergens. Allergenicity does not appear to be an inherent property of proteins although all proteins are certainly capable of provoking immune responses under selected circumstances of exposure. Some allergenic foods, such as peanuts, eggs, milk, shrimp, and soybean contain multiple allergens, while other foods, such as Brazil nut, appear to contain only a single major allergen (Sathe et al., 2016). Major allergens are generally defined as proteins for which 50% or more of the allergic patients studied have specific IgE. Food allergens tend to fall into certain functional classes such as some of the pathogenesis-related proteins, certain types of seed storage proteins, or EF hand proteins (Lorenz et al., 2015; Radauer et al., 2008). For example, the 2S albumins, storage proteins rich in sulfur-containing amino acids, are major allergens in peanuts, Brazil nuts, sesame seeds, walnuts, sunflower seeds, and mustard. Similarly pan allergens exist across many species of fish (parvalbumin) and crustacean shellfish (tropomyosin). However, both fish and crustacean shellfish also possess other protein allergens (Sathe et al., 2016).

Prevalence

The overall prevalence of IgE-mediated food allergies is not precisely known and appears to be increasing in many countries for reasons that are also not entirely clear. The overall prevalence of food allergies among infants and children in the United States and Australia falls in the range of 5–10% (Gupta et al., 2011; Peters et al., 2017). Although many studies indicate that the prevalence of food allergies is higher among children than adults, recent evidence in the United States indicates that the prevalence of food allergies among adults is approximately 10% (Gupta et al., 2019). In a comprehensive study involving allergy centers in 8 different countries across Europe, the self-reported prevalence of food allergy ranged from 2% to 37% of survey respondents, while, on follow-up, the probable prevalence of food allergy ranged from a low of 0.3% in Greece to a high of 5.6% in Switzerland (Lyons et al., 2019). The bases for these differences are not entirely clear.

The prevalence of allergies to specific foods is also not precisely known. Based upon a telephone survey, which is probably less accurate than diagnostic evaluation, shrimp allergy appears to be the most common food allergy in the United States at 1.9% (Sicherer et al., 2004; Gupta et al., 2019). In 7 of 8 EU countries, the prevalence of shrimp allergy ranged from 0.35–0.82% with no shrimp allergy observed in Greece. Peanut and tree nut allergies were believed to affect about 0.75% and 0.6% of the overall population in the United States based on a survey published in Sicherer et al. (2010), while the prevalence leapt to 1.8% for peanut and 1.2% for tree nuts based on a survey published in Gupta et al. (2019). Peanuts are less commonly consumed in some European countries. The prevalence of peanut allergy was very low in Iceland (0%) and Greece (0.02%) but was higher in other countries including 0.45% in Spain and 0.37% in Switzerland (Lyons et al., 2019). The prevalence of milk allergy among young infants is more consistent among countries ranging from 0.5–2.2% among studies done in the United States, Israel, Denmark, and in a European birth cohort (Flom and Sicherer, 2019; Lam et al., 2008). While milk allergy has historically been considered as relatively uncommon in adults (Flom and Sicherer, 2019), several recent studies have indicated a high prevalence of 2.0–2.4% among United States adults (Gupta et al., 2019; McGowan and Keet, 2013). In the study of Gupta et al. (2019), 22% of adults who reported milk allergy also indicated an adult onset of this allergy. Two-thirds of adults with cows' milk allergy reported experiencing severe symptoms (Lam et al., 2008). Sorting out the true prevalence of food allergies in countries around the world will require considerable effort that will likely be made more difficult by the increasing prevalence of food allergies in many locations. Certainly the factors associated with the low prevalence of food allergies in Greece would be worthy of future investigation.

An increase in the prevalence of IgE-mediated food allergies is most apparent in developed countries, although variability is noted between developed countries such as Switzerland and Greece. The prevalence appears lower in less developed countries but is, as yet, poorly understood making firm comparisons difficult. Multiple factors may be involved in the increased prevalence. Certainly improvements in diagnosis mean that fewer cases are overlooked. The increased general cleanliness of the home environment is another factor that led to the promulgation of the hygiene hypothesis (Julge et al., 2001). The prevalence of food allergies is higher in urban environments than rural areas perhaps because the immune system is busy counteracting bacteria that are more prevalent on farms (Botha et al., 2018). The hygiene hypothesis has more recently evolved into a recognition that the intestinal microbiota play an important role in the balance between tolerance and allergy to foods (Shu et al., 2019). The microbiota is influenced by another factor, the increase in infants born by Caesarean sections, which is associated with an increase in food allergies (Koplin et al., 2008). After Caesarean birth, the infant's intestinal tract is devoid of beneficial maternal microbiota. Weaning practices and epigenetic factors (see Section "Prevention") may be additional important factors in prevalence.

Persistence

Many infants and young children outgrow their IgE-mediated food allergies through the eventual development of oral tolerance. Allergies to some foods, such as cows' milk and eggs are more frequently outgrown than allergies to other foods such as peanuts (Savage et al., 2016). The time period for development of tolerance ranges from a few months to several years from the time of the onset of the food allergy. As many as 80% of food-allergic children are able to tolerate the offending food by the age of 3–4 years (Peters et al., 2017; Savage et al., 2016). While peanut allergy tends to be very persistent, perhaps 20% of peanut-allergic children do

ultimately become tolerant. While milk allergy is frequently outgrown, some individuals do fail to achieve tolerance and become milk-allergic adults. However, food allergies can have their initial onset in adulthood in some cases (Gupta et al., 2019). Studies on milk- and egg-allergic children indicate that some may first become tolerant of certain processed forms of milk and egg e.g., baked foods, though being still sensitive to less heated forms of milk and eggs such as pasteurized milk and scrambled egg, although more rigorous proof of this hypothesis is needed (Lambert et al., 2017).

Prevention

The prevention of allergic sensitization in infants would counteract the development of IgE-mediated food allergies. Since most infants have a low risk of development of food allergies, the implementation of effective prevention strategies requires the early identification of those high-risk infants most likely to develop IgE-mediated food allergies. High-risk infants include those infants born to parents with histories of allergic disease of any type (pollens, mold spores, animal danders, bee venoms, food, etc.). Several strategies have been advanced for the prevention of allergic sensitization in high-risk infants. For many years, a pragmatic approach of excluding the infant from exposure to commonly allergenic foods. This strategy was coupled with breast-feeding for an extended period, the possible use of hypoallergenic infant formulae, and the exclusion of commonly allergenic foods from the diet of the nursing mother and possibly during pregnancy (Zeiger, 2003). While this approach seemed logical, it was not based upon clinical evidence of its efficacy (Sicherer, 2002). Furthermore, the prevalence of food allergies continuously increased while this strategy was being widely practiced. Exclusive breast-feeding may only delay and not prevent the development of IgE-mediated food allergies. High-risk infants may be sensitized through cutaneous exposure to food allergens on abraded, eczematous skin (du Toit et al., 2018) so avoidance of exposure to the allergen by the oral route alone is likely not sufficient. Maternal avoidance diets during pregnancy appear unwarranted and such exposure is more likely to assist in tolerance induction in the infant (Fujimura et al., 2019). Maternal avoidance during exclusive breast-feeding may decrease the risk of allergic sensitization in the infant but this could be due to the possibility of environmental exposure to the allergen via the skin (Fujimura et al., 2019). In nursing mothers, allergenic food proteins consumed in her diet may get absorbed and passed into breast milk (Schocker et al., 2016). This route of exposure could possibly sensitize the infant. Overall, the avoidance strategy seems to pale in comparison to the benefits of early introduction of allergenic foods.

Recent evidence demonstrated that the early introduction of peanut into the diets of high-risk infants (those having eczema and egg allergy at 4-months) would dramatically lower the likelihood for development of peanut allergy (du Toit et al., 2015). A similar strategy has been applied to other allergenic foods with mixed success (Fisher et al., 2018). Further research is needed to refine the factors involved in success for this strategy such as the age of the infant, the specific foods involved, and the degree of processing of the food. Widespread recommendations have now been made to feed peanuts to infants at an early age as a preventive measure. Breast-feeding is still advocated but with supplementation with peanuts or perhaps other allergenic foods. Commercially, several weaning foods are now available to allow the early introduction of peanuts and other commonly allergenic foods to young infants.

Nutrition could play a role in prevention of food allergies as well. Factors such as vitamin D, omega-3 fatty acids, folate, and antioxidants have been proposed to have effects on the development of food allergies (Sicherer and Sampson, 2018). Specific genetic loci have been identified that are associated with peanut allergy (Hong et al., 2015). In milk-allergic individuals, altered DNA methylation was found in several loci associated with T cells that are critically involved in development of IgE-mediated food allergy (Hong et al., 2016).

The use of probiotic bacteria and prebiotic infant formula may also help to lessen the likelihood of allergic sensitization (Berni Canani et al., 2019; Jeurink et al., 2013). Many of the studies with administration of probiotic bacteria have been conducted in animal models and their protective effects require further elucidation. Infant formula containing prebiotic oligosaccharides that promote the growth of beneficial microbiota in the intestinal tract have offered promising results (Jeurink et al., 2013). Commercial formulae are on the market.

Hypoallergenic infant formulae will also prevent the development of food allergies in high-risk infants in the early months of life in situations where exclusive breast-feeding is not possible. However, these formulae, especially extensively hydrolyzed and/or elemental formulae, are more often used to prevent reactions after sensitization has already occurred. The use of partial whey hydrolysate formula has been advocated for prevention (Vandenplas et al., 2019). Partial hydrolysates are more palatable to the infant.

Diagnosis

The diagnosis of food allergies is typically approached in a stepwise fashion (Boyce et al., 2010; Sicherer and Sampson, 2018). The diagnosis of food allergies by an allergist is often critical because parental diagnosis and self-diagnosis are often incorrect leading to identification of the wrong, incorrect foods or the identification of too many foods as allergens. The diagnosis begins with the physician taking a careful history of the patient's adverse reactions, taking note of the foods eaten immediately before the onset of symptoms, the amount of various foods consumed, the type, severity, and consistency of symptoms, and the time intervals between eating and the onset of symptoms. Sometimes, histories are needed from several episodes to reach a probable diagnosis. Oral challenge tests with the suspected food(s) may be used to establish with certainty the role of a specific food in the reaction. The double-blind, placebo-controlled food challenge (DBPCFC) is the most definitive clinical approach to document the cause-and-effect relationship with a particular food. History alone can be sufficient to make the diagnosis in some situations if the

cause-and-effect relationship is particularly compelling. A positive challenge test indicates that the food is associated with the adverse reaction but cannot be used to determine if IgE antibodies are involved. The diagnosis of an IgE-mediated mechanism can be made with either the skin prick test or a blood test for the presence of food-specific IgE antibodies.

Treatment

The specific avoidance diet is the primary means of treatment for IgE-mediated food allergies (Taylor et al., 1999; Grimshaw, 2006). For example, if allergic to peanuts, do not eat peanuts. Some individuals are allergic to more than one food which complicates the avoidance diet. With IgE-mediated food allergies, low amounts of the offending food can provoke reactions. Thus, the construction of a safe and effective avoidance diet can be quite difficult. Ingredients derived from commonly allergenic foods must also be avoided in many cases such as casein or whey from milk or semolina from wheat. The sources of ingredients derived from commonly allergenic sources must be labeled in many countries and food-allergic consumers are advised to avoid them even in situations where the risks may be quite small. In the United States, source labeling is not necessary for refined oils from allergenic sources such as peanut oil or soybean oil because these ingredients do not contain enough of the allergenic protein to provoke reactions. Less refined oils may contain sufficient allergenic protein to pose a risk to allergic consumers. Careful reading and complete understanding of food labels is critical to the implementation of safe and effective avoidance diets. Of course, the manufacturers of packaged foods have the responsibility to assure that the label statements on packages are accurate. Occasionally, errors are made by food processors that result in the presence of undeclared residues to allergenic foods in a packaged food. The contamination of food with another from the use of shared food processing equipment is one of the most common errors occurring in food manufacturing. However, restaurant and other food service meals can present an even bigger challenge for food-allergic individuals. Residues of allergenic foods can arise from the use of shared food preparation equipment (utensils, cooking surfaces, pots and pans, etc.). Additionally, the accurate identification of all of the ingredients in food service and restaurant meals can sometimes be quite difficult and such foods are not labeled in most countries. As a result, many inadvertent exposures occur among consumers who are attempting to avoid their offending food(s).

Cross-reactions are another perplexing issue for food-allergic consumers as they attempt to develop effective avoidance diets (Kazatsky and Wood, 2016). Cross-reactions can occur but do not inevitably occur between closely related foods. For example, many individuals are allergic to peanuts, but most of these individuals are not allergic to other legumes such as soybeans, lupine, peas, and green beans (Chan et al., 2019). Many peanut-allergic individuals are sensitized to other legumes but most can ingest these other legumes with no ill effects. Lupine, a legume which is unfamiliar to many consumers cross-reacts with peanuts in some allergic individuals (Chan et al., 2019). As a result, peanut-allergic individuals are often advised to avoid lupine even though most will not react. Cross-reactions frequently occur among the various crustacea (shrimp, crab, lobster and crayfish) and among species of fish (Pedrosa et al., 2016; Kobayashi et al., 2016). Cows' milk and goats' milk invariably cross-react as do eggs from various avian species (Kazatsky and Wood, 2016). Cross-reactions can also occur between foods and other environmental allergens. The most common examples are the cross-reactions that occur between some fresh fruits and vegetables and certain pollens allergies in some individuals (Werfel et al., 2015) and the cross-reactions that occurs in a few individuals with allergies to natural rubber latex with several foods including banana and chestnut (Raulf-Heimsoth et al., 2007).

Pharmacological approaches can be used to treat the symptoms of allergic reactions. In particular, epinephrine (also known as adrenalin) is prescribed to individuals who experience life-threatening food allergies (Greenhawt et al., 2019). The early administration of epinephrine after inadvertent exposure to the offending food can be life-saving for such patients. Antihistamines and other medications can be used to treat less-serious symptoms of food allergies (Boyce et al., 2010; Kobernick et al., 2015).

Immunotherapy (IT) has emerged as a promising therapy for the control of food allergies (Burks et al., 2018). With IT, small doses of the allergenic food are administered to the food-allergic patient over time causing the patient to become progressively more tolerant to the offending food. In most cases, IT is not a curative treatment because most patients do not achieve sustained unresponsiveness. Instead, patients must continue to regularly consume a maintenance dose of the allergenic food to achieve some level of non-responsiveness to the food. The up-dosing protocol must be approached carefully to avoid eliciting adverse reactions. In the end, the patient may not be able to consume large quantities of the food but will be protected from experiencing reactions to small doses encountered from contamination of one food with another during harvesting, processing or preparation. The development of additional treatments for food allergies are being pursued (Burks et al., 2018).

Minimal eliciting dose (Threshold)

In some individuals with IgE-mediated food allergies, reactions can be triggered by very low doses of the offending food. The low threshold for the offending food complicates effective avoidance as great care must be taken. The low eliciting dose results from the interaction of a rather small amount of allergen with IgE antibodies on the surfaces of mast cells and basophils which stimulates the release of large quantities of biologically active mediators. Accordingly, exposure to a small dose of the allergen can elicit a clinically significant reaction.

With avoidance diets, the complete avoidance of the offending food must be emphasized to all allergic individuals. However, clinical research has documented that minimal eliciting or threshold doses do exist below which allergic individuals will not experience adverse reactions. Low-dose DBPCFC can be used to determine the threshold dose for an individual patient to a specific food. For peanut, a wide range of individual threshold doses from 0.4 mg up to 10 g of whole peanut has been observed (Taylor and

Baumert, 2010). Individual threshold doses could be collected and used by public health authorities to establish population thresholds (Madsen et al., 2009). Dose-distribution modeling has been advocated as a scientifically based, transparent approach to the estimation of safe doses for allergic individuals using the data acquired from existing challenge trials (Gendel et al., 2008). Individual threshold data have been collected using consistent criteria and modeled to predict safe population thresholds for many of the most common allergenic foods (Remington et al., 2020; Westerhout et al., 2019). These population thresholds have been demonstrated to be safe for peanut-allergic individuals (Hourihane et al., 2017). Population thresholds could be used to guide food-allergic consumers in the construction of safe, effective avoidance diets and labeling and other control strategies used by the food industry.

Occurrence of allergic reactions

Since no cure exists for IgE-mediated food allergies, the prevention of reactions focuses on avoidance diets. However, food-allergic consumers will occasionally experience reactions by inadvertent consumption of the offending food. Records from emergency rooms indicate that tens of thousands seek emergency treatment for food allergy reactions each year (Clark et al., 2011). In Canada, peanut-allergic individuals studied over a 10-year period had a 12.4% annual incidence rate of accidental exposures to peanut (Cherkaoui et al., 2015). Many of these Canadians did not seek medical attention for their reaction even if it involved modest to severe symptoms (Cherkaoui et al., 2015) so the rate of presentation in emergency rooms likely underestimates the incidence of allergic reactions. In the Netherlands, 73 of 157 adult patients experienced allergic reactions to a variety of food products during a 1-year period (Blom et al., 2018). The factors leading up to these visits are poorly understood. Certainly, a small fraction of emergency room visits occur among individuals who are experiencing an allergic reaction to food for the first time. But most of these reactions likely occur among individuals who are aware of their food allergy and who should be avoiding the offending food. Individual who had received counseling from an allergist and received an epinephrine prescription were less likely to show up in emergency rooms for treatment of a food allergy reaction (Clark et al., 2014). Evidence also suggests that some individuals have repeated emergency room visits for food allergy reactions (Clark et al., 2014).

Food allergy reactions can occur in any location where food is sold or eaten (Taylor and Baumert, 2010). Homes and restaurants are the most frequent locales for such reactions. Obviously, the food-allergic individual or their caregiver could make an error that leads to inadvertent ingestion of the offending food. Failure to read or understand food labels can be a contributing factor. Avoidance diets require constant vigilance and errors are likely to happen. The frequency of such errors is unknown.

However, food manufacturers or restaurants may also contribute to food allergy reactions. Prevention of errors by food manufacturers or restaurants has become an important public health focus.

A variety of food manufacturing errors can occur including placing the incorrect product in the package, the failure to adequately clean shared equipment, the use of re-work (a common practice in certain segments of the industry involving the incorporation of left-over or misformulated quantities of a food product into subsequent batches of related products with identical or related formulations), and the inadvertent addition of an ingredient that is not supposed to be in the formulation. However, with packaged foods, the majority of food ingredients are declared on the ingredient statement on the label. Additionally, many food processors have begun to add precautionary allergen labeling (PAL) to food products including such terms as 'made on shared equipment with peanuts' or 'may contain peanuts'. This sort of labeling alerts allergic consumers to the potential presence of residues on allergenic foods in a product. However, the recent proliferation of PAL has led some food-allergic consumers to begin to ignore these statements (Allen and Taylor, 2018). In some countries, products with PAL statements frequently do not contain detectable allergen residues (Allen and Taylor, 2018) while consumers in other countries frequently experience allergic reactions from consumption of products with PAL (Blom et al., 2018).

Restaurants and other foodservice facilities constitute another big challenge for food-allergic consumers (Taylor and Baumert, 2010). In most countries, foods in restaurants are not labeled although allergen labeling is required in European countries. Wait staff sometimes fail to provide correct information on menu components. Many adverse reactions have occurred in such settings. Additionally errors can occur in food preparation including the use of shared cooking/serving equipment or cooking surfaces or cooking media and mistakes or substitutions in adherence to recipes.

Regulations

Public health agencies such as the US Food & Drug Administration regulate the labeling of packaged foods (Taylor and Baumert, 2015). As noted, the ingredient statements on packaged foods identify the vast majority of the allergenic foods or the ingredients sourced from such foods. Regulations differ around the world but the clear labeling of commonly allergenic foods is a key component of regulations in most countries.

The enforcement of existing regulations is another task for the public health agencies. In the United States, the wider recognition of food allergies has extended to FDA and other regulatory agencies. One of the fastest growing areas of recalls of packaged foods in the United States is the undeclared presence of allergenic foods. Improved methods for the detection of residues of allergenic foods have been pivotal to the investigation of allergic incidents and the enforcement of labeling regulations.

Detection of allergenic food residues

Reliable methods exist for the detection of the presence of undeclared or unwanted allergen residues in foods and food ingredients (Prado et al., 2016). The food industry uses the detection tools to assure that their manufacturing practices are adequate to eliminate the presence of unwanted allergen residues in other foods. When residues cannot be effectively and consistently eliminated, then PAL can be used. The regulatory agencies use the detection methods for enforcement of labeling provisions on packaged foods and to investigate alleged reactions that might be attributable to undeclared allergen in packaged foods. Commercial enzyme-linked immunosorbent assays or ELISAs with detection limits in the low ppm (mg kg^{-1}) range are available for the detection of residues of peanuts, soybeans, egg, cows' milk, almonds, gluten (wheat, rye, barley), walnuts, cashews, pistachios, pecans, hazelnuts, Brazil nuts, macadamia nuts, crustacean shellfish, mustard, lupine, and buckwheat. Polymerase chain reactions assays are also available for the detection of DNA from allergenic food sources. Mass spectrometry methods are being developed also for the specific detection of selected proteins from allergenic food sources.

Effects of food processing on allergenicity

Food processing operations have limited effects on the allergenicity of most of the commonly allergenic foods since the allergenic food proteins tend to be remarkably stable to food processing conditions (Sathe and Sharma, 2009; Cabanillas and Novak, 2019). Food-allergic individuals react to processed foods so allergens must be stable to food processing with some exceptions. For example, some of the allergens in fruits and vegetables are heat-sensitive. Additionally, many food allergens tend to be resistant to proteolysis allowing these proteins to survive digestive processes and arrive in the intestinal tract in immunologically active form (Lorenz et al., 2015). Thus food allergens may survive, in whole or in part, the acid and enzymatic hydrolysis methods used to prepare protein hydrolysates often used as food ingredients. Hypoallergenic infant formula can be manufactured with extensive hydrolysis of milk proteins but is one of the few examples where processing has been used commercially with the intent of drastically reducing or eliminating allergenicity (Host and Halken, 2014). The removal of almost all protein residues in edible oil refining serves as another example.

Food-allergic individuals may also vary in their susceptibility to processed forms of commonly allergenic foods. With milk and egg, some children develop tolerance to baked products containing milk and egg proteins (Lambert et al., 2017). These individuals seem to be reactive to allergens in milk and egg that are denatured by the heat used in the baking process. But other milk- and egg-allergic children do not share this experience and remain reactive to both baked and unbaked forms of milk and egg.

Celiac disease

Celiac disease is also known as celiac sprue, non-tropical sprue, or gluten-sensitive enteropathy. Celiac disease occurs in sensitive individuals upon the consumption of wheat, rye, barley, and related grains as illustrated in Table 2. This illness is a good example of delayed hypersensitivity reactions associated with food.

Mechanism

Celiac disease is associated with a cell-mediated, localized inflammatory reaction in the intestinal tract (Schuppan et al., 2009). The inflammatory response results in the so-called 'flat lesion' in the small intestine. The absorptive epithelium lining the small intestine becomes damaged by the inflammatory process resulting in a decreased number of epithelial cells that are critical to digestion and the absorption of dietary nutrients. Thus, the absorptive function of the small intestine is compromised leading to the development of a malabsorption syndrome. The inflammatory response in the gut is characterized by villous atrophy along with crypt hyperplasia, lymphoid infiltration of the epithelium, edema of the lamina propria, and the impaired epithelial absorptive function. Increased fluid secretion and enhanced permeability of the epithelium are also noted. A defect in mucosal processing of gliadin

Farro

(one of the gluten protein components from wheat) in celiac patients appears to provoke the generation of toxic peptides that contribute to abnormal immunologic response and the subsequent inflammatory reaction.

Symptoms and sequelae

Celiac disease results in a severe malabsorption syndrome characterized by diarrhea, bloating, weight loss, anemia, bone pain, chronic fatigue, weakness, various nutritional deficiencies, muscle cramps, and, in children, failure to thrive. While the risk of severe reactions is low, untreated celiac disease is associated with considerable discomfort in many celiac sufferers. Individuals suffering from celiac disease for long periods are also at increased risk to development of T cell lymphomas. Celiac patients are also more likely than others to have various other diseases especially diseases of the autoimmune nature including dermatitis herpetiformis, thyroid diseases, Addison's disease, pernicious anemia, autoimmune thrombocytopenia, sarcoidosis, insulin-dependent diabetes mellitus, IgA nephropathy, and Down's syndrome (Diamanti et al., 2016).

Causative factor

The prolamin protein fractions of wheat and related grains are implicated in the causation of celiac disease (Cabanillas, 2020). The prolamin fraction of wheat is known as gluten, so celiac disease is sometimes referred to as gluten-sensitive enteropathy. In wheat, gliadin, the alcohol-soluble fraction of gluten, is involved in the elicitation of celiac disease. Glutenin, the alcohol-insoluble fraction is also likely involved however. The prolamins are the major storage proteins in these grains, so all of these grains contain ample gluten and are considered hazardous for celiac sufferers.

Prevalence and persistence

The prevalence of celiac disease on a global basis is uncertain. In the United States, the prevalence is considered to be approximately 1% of the population (Green et al., 2015). The diagnosis of celiac disease can be rather difficult. Celiac disease appears to be latent or subclinical in some individuals with symptoms only appearing occasionally. The clinical presentation of celiac disease is quite variable with anemia and osteoporosis as two of the more frequent manifestations in adults in the United States (Green et al., 2015). Serological and endoscopic histological approaches are often needed to confirm the diagnosis of celiac disease.

Management and minimal eliciting dose

Celiac disease is treated by the implementation of a gluten avoidance diet (Green et al., 2015). Affected individuals should avoid all sources of wheat, rye, barley or related grains including a wide variety of common food ingredients derived from these grain. The need to avoid ingredients that do not contain detectable protein from the implicated grains is somewhat debatable, but widely practiced. Most of these individuals also avoid oats, but that is likely wise considering the frequent contamination of oats with wheat from shared farms, harvesting equipment, and storage facilities. Gluten-free foods are available with increasing frequency in the marketplace. The definition of gluten-free in most countries is below 20 ppm gluten.

The minimal eliciting dose for wheat, rye, barley and related grains among celiac sufferers is unknown. Several studies have concluded that levels of 10 mg of gluten per day will be tolerated by most patients with celiac disease (Catassi et al., 2007; Akobeng and Thomas, 2008).

Conclusion

While food allergies affect a small percentage of the population, reactions can range in severity from mild to life-threatening. Food allergies are caused primarily by naturally occurring proteins in foods. Food allergies can be triggered by rather small amounts of the offending foods.

Introduction

Celiac disease is an immune-mediated enteropathy that occurs in genetically susceptible persons. The disorder is characterized by intolerance to gluten-containing proteins found in different but related grains, such as wheat, rye, and barley. Another cereal grain, oats, may be contaminated by other gluten-containing grains. The disorder typically presents with diarrhea, nutrient malabsorption, and weight loss due to a mucosal inflammatory process that extends for a variable extent from the most proximal duodenum into the distal jejunum and ileum. It is possible that the severity of the individual inflammatory response to the offending proteins, the timing of its appearance, and its extent and localization within the small intestine are genetically programmed. In recent years, the disorder has been increasingly recognized in the absence of significant gastrointestinal symptoms, with a recorded prevalence rate (based on serological studies) of up to 2% in many countries. Not only is celiac disease common, but there is an increased appreciation that celiac disease is a phenotypically heterogeneous disorder. Increased recognition of celiac disease may reflect a true increase in incidence per se, but other factors likely play a more significant role. Increased diagnostic awareness among clinicians is evident coupled with widespread use of serological screening tests. Finally, in the eye of the public, perhaps more than ever before, the disorder has emerged from obscurity into the popular spotlight (Gujral et al., 2012).

Clinical features

Often, the disorder presents with diarrhea, multiple nutrient deficiencies, and weight loss. In children, failure to thrive with short stature and delayed puberty may occur. In recent years, however, it has become increasingly appreciated that a wide array of clinical presentations may develop, often without overt intestinal features. Anemia solely due to iron or folate deficiency may occur (Freeman, 2015a). In addition, isolated calcium deficiency has been noted along with hypoalbuminemia and peripheral edema, osteomalacia, or osteoporosis. Occasionally, unexplained chronic liver disease may develop, and several neurological disorders, such as dementia (Freeman, 2008), along with reproductive changes have been described (Freeman, 2015c). These or other extraintestinal disorders may actually dominate the clinical presentation, particularly endocrine disorders (Freeman, 2016a,b) such as autoimmune thyroid disease, insulin-dependent diabetes and other unusual disorders like, acetylcholine receptor antibody positive myasthenia gravis, and systemic lupus erythematosus.

Because celiac disease has been traditionally defined as a gluten-sensitive disorder, a definitive diagnosis ultimately depends on demonstration of a response to a gluten-free diet (Freeman, 2008). A biopsy of the small-intestinal mucosa is traditionally done to demonstrate the typical histopathologic features of untreated celiac disease. Serological antibody markers are usually positive, including antibodies to tissue transglutaminase and endomysium. After treatment with a gluten-free diet, resolution of the diarrhea and weight gain usually occur along with normalization of serological studies. Normalization of abnormal small-intestinal biopsy changes follows, even months to years later on a gluten-free diet (Freeman, 2017a).

[☆]Change History: October 2021. Hugh J Freeman updated the text and references to this entire chapter.

Age, sex, race, and global distribution

Although celiac disease is often detected in childhood, the disorder is most frequently diagnosed in adults, particularly between ages 25 and 45 years. Some studies have suggested that the clinical onset is bimodal, with the initial peak developing at 8–12 months of age, and the second during the third to fourth decades of life. In recent years, the disease has also been frequently recognized for the first time in the elderly (Freeman, 2015a), even in octogenarians! In adult age groups, there is a preponderance of females, although, in the elderly, the ratio of females to males appears to be more equivalent. In part, this may reflect the greater likelihood that females, as young adults, often seek medical care more frequently and at an earlier age than males. In addition, the necessary genetic markers, the HLA haplotypes DQ2 and DQ8, are more frequent in female compared to male celiacs (i.e., 94% vs 85%). In the few DQ2- and DQ8-negative celiac disease patients, a male excess has been noted. Factors that appear to lead to precipitation of celiac disease in the genetically predisposed have not been well defined, but environmental factors, including viral infections (e.g., adenovirus and rotavirus) and an altered immune state, associated with surgical procedures (i.e., post-gastrectomy, post-colectomy), pregnancy, or the puerperium, have been noted.

In the past, celiac disease was well described in Caucasians, especially from European centers, particularly the United Kingdom, Scandinavia, and Italy. Some believed that the west of Ireland, with about one individual with celiac disease in 300 persons, was the most frequent geographic site, and early published studies suggested a decreasing gradient in prevalence from the northwest to southeast of Europe. In part, this impression reflected limitations in data on celiac disease in most countries. For example, little information was available for most countries in North and South America, although the disease was suspected to be common in some countries there; it was attributed to emigration from Europe, particularly to Canada and Argentina. Interestingly, in the United States, celiac disease was considered to be a relatively rare disorder only a few decades ago. The disease has also been rarely reported from Asia, particularly China and the Indian subcontinent, or from North Africa. In recent years, however, a much wider global occurrence of celiac disease has become better appreciated.

The highest reported rates to date have come from centers in Finland. Other European countries and countries with immigration from Europe, especially the Americas and Australia, also all have high rates. Celiac disease has now also been more frequently recorded in several different Asian countries, including India and Sri Lanka, as well as China, the Middle East, and North Africa. Finally, Asian immigrant populations and their descendants in the United Kingdom and Canada, along with First Nations populations in Canada, have been recorded with celiac disease.

Although up to 2% of the general populations of some countries may be affected, the risk is much greater in first-degree relatives of affected sibling pairs (17%), monozygotic twins (75%), and HLA-identical siblings (40%). Indeed, the single most important risk factor for celiac disease is a first degree relative with already-defined celiac disease, especially a sibling.

History

Celiac disease is believed to have initially appeared in the Neolithic period with the evolution of humans from the hunter-gatherer phase to an agrarian or farming phase, with the appearance of modern crop cultivation methods in different regions to provide food and a survival advantage. Indeed, even now, varieties of wheat around the world have now been genetically traced to the Eikhorn form of wild wheat from the Fertile Crescent area, especially in eastern Turkey.

In 1856, Francis Adams delivered a lecture to the Sydenham Society that represented a translation of a Greek manuscript on the 'Coeliac Affection' from the second century by Aretaeus, a physician residing in Cappadocia (in eastern Turkey). The word 'celiac' appears to have arisen from a Greek word, 'koiliakos,' meaning 'abdominal.' Aretaeus believed that the cause of the diarrhea in adults with this disorder, usually females, was a 'lack of heat' needed to digest food.

In 1887, Samuel Gee provided a more modern description of the disorder in children during a lecture at the Hospital for Sick Children, located on Great Ormond Street in London. Gee believed that the disease may be curable, specifically with diet, and noted the exacerbations of symptoms in children with lactose-containing products. In 1908, Herter, a physician from the United States, further noted in detail 'intestinal infantilism,' emphasizing the deleterious effects of the disorder on growth in affected children. Both pediatricians were ultimately recognized for their descriptive accounts of childhood celiac disease with the appearance of the eponym 'Gee-Herter disease.' In 1924, Haas, another pediatrician from the United States, promoted a banana diet for the disorder, and this persisted as a popular form of celiac disease treatment for decades.

The next significant step in the historical emergence of this disease came during World War II. A Dutch pediatrician, Dicke, noticed that children with celiac disease seemed to clinically improve with fewer deaths during periods of famine and scarcity of wheat flour, in particular the winter of 1944 (the so-called *hongerwinter*). As wheat became increasingly available again, the high death rate documented in these children recurred. Later, Dicke and his colleagues developed a laboratory method for measurement of fat in fecal material and demonstrated increased fecal fat excretion with ingestion of wheat flour and reduced excretion when wheat flour was removed from the diet. In 1952, Anderson and her colleagues from the United Kingdom suggested that gluten was the actual component in wheat that caused worsening of the disease.

Up to this time, most information on the pathology of the small intestine in celiac disease had been accumulated using autopsy material. This was not satisfactory because of the rapid autolytic mucosal changes that appear during the immediate postmortem period. In 1954, Paulley provided the first histopathological description of atrophied villi using surgical specimens. Almost

immediately, an explosion in instrumentation for exploration of the luminal intestinal tract occurred. As a result, mucosal biopsies were collected with small-intestinal capsules and with multipurpose and hydraulic instruments, and, concomitantly, the emergence of endoscopic imaging permitted sampling under direct vision. Precise clinical and histopathological descriptions of the disease were developed based on its gluten-sensitive nature as well as recognition that the biopsy changes were not specific for celiac disease. In addition, more reproducible and more specific serological assays for population screening were developed. Extraintestinal disorders, such as dermatitis herpetiformis, were explored, and an improved appreciation for clinical complications of celiac disease emerged, including lymphoma, carcinoma, and collagenous colitis. In recent years, a much improved understanding of the complex immunopathogenesis of celiac disease has been detailed, with efforts in several centers to develop alternative therapies.

Diagnosis of celiac disease

Two criteria, based on the concept that celiac disease is a gluten-sensitive enteropathy, have emerged for a definitive diagnosis of classical celiac disease. The diagnosis is based on two sequential criteria: first, a small-bowel biopsy that shows the histopathological features of untreated disease; and, second, documentation of a response to a gluten-free diet. The biopsy features of celiac disease are listed in detail in Table 1 (Figs. 1–5).

After a biopsy has documented changes of untreated celiac disease, a gluten-free diet is instituted. An unequivocal clinical and/or histopathological response is usually necessary to establish a definitive diagnosis. Most often, the diarrhea should resolve and weight gain should occur. In some with few or no symptoms, it may be necessary to repeat biopsies from similar sampling sites to demonstrate an improved biopsy appearance. In recent years, some have estimated that over 50% of those with celiac disease may now actually be classified as overweight or obese. Even in these patients, it was possible to demonstrate weight gain in response to a gluten-free diet.

Fig. 1 Small-bowel mucosal biopsy showing severe ‘flat’ changes characteristic of celiac disease, or so-called total villous atrophy (see text). Villi are rudimentary, crypts are elongated with an increased mitotic index, and increased numbers of mucosal lymphocytes and plasma cells are evident. Hematoxylin and eosin (H & E), magnification $\times 200$.

Table 1 Biopsy features of celiac disease (gluten-sensitive enteropathy and celiac sprue; see Figs. 1–5).

Severe ‘flat’ lesion

Absent or rudimentary villi, crypt epithelial hyperplasia with an increased epithelial cell mitotic index, increased inflammatory cell content of the lamina propria region in the mucosa, intraepithelial lymphocytosis, cuboidal (rather than columnar) epithelial cells; CD3 and CD8-positive lymphocytes predominate in the mucosa, particularly in the intraepithelial lymphocyte compartment.

Another term is ‘crypt hyperplastic villous atrophy.’ Similar to a ‘Marsh 3’ lesion.

Moderate lesion

Similar changes, but not as pronounced, with only limited but definite alterations in the architecture of the villous.

‘Variably severe’ architectural change. Similar to a ‘Marsh 2’ lesion

Mild lesion

Villi are unaltered or minimally changed in size with a loss of epithelial cell polarity and marked increase in intraepithelial lymphocytes

Marginal increase in lamina propria region cellularity. Similar to a ‘Marsh 1’ lesion.

Fig. 2 Endoscopic biopsies showing moderately severe changes of celiac disease, or so-called partial villous atrophy (see text). One fragment also shows Brunner's glands typical of biopsies taken from the duodenum. H & E, magnification $\times 40$.

Fig. 3 CD-3-positive intraepithelial and lamina propria lymphocytes in celiac disease mucosa (see text). Immunohistochemical stain, magnification $\times 400$.

Fig. 4 CD-8-positive intraepithelial and lamina propria lymphocytes in celiac disease mucosa (see text). Immunohistochemical stain, magnification $\times 400$.

Fig. 5 Endoscopic mucosal biopsy showing mild changes in villous architecture with increased intraepithelial lymphocytes. About 10% of patients diagnosed with celiac disease may have only limited changes (see text). H & E, magnification $\times 200$.

Serological testing has become very useful as a screening measure for celiac disease, particularly newer IgA and IgG antibody methods (i.e., anti-tissue transglutaminase). However, these cannot be relied on solely to establish a diagnosis. In genetically at-risk children, for example, studies have shown the spontaneous disappearance of these antibodies in a normal diet. With immunoglobulin deficiency syndromes, false negative serological testing may also occur (e.g., IgA deficiency). If there is a clinical suspicion of celiac disease, a biopsy should be done to confirm the disorder. This includes serologically positive patients since false positive tests have occasionally been recorded in adults with normal biopsies.

The biopsy changes in classical celiac disease are prominent in the most proximal small intestine, and less so in the more distal small intestine. These changes may also be classified based on the degree of altered architecture or a combination of pathological features. Some degree of intraobserver and interobserver disagreement is common in biopsy interpretation and in the interpretation of the degree of biopsy changes. However, this error factor appears to be more significant with more cumbersome classification schemata, even among expert pathologists with a special interest in the interpretation of intestinal biopsy material.

In classical celiac disease, the architectural changes usually appear as a 'severe lesion' (or 'flat lesion') with rudimentary villi, increased mucosal and intraepithelial inflammatory cells, and hyperplasia of crypt epithelial cells. These changes may revert to normal with a strict gluten-free diet. Sometimes, this improvement may require prolonged periods of time to occur, even months to years, especially in older adults. In some, however, less severe or more variable degrees of inflammatory change are noted. In a 'mild lesion,' only limited alterations in villus architecture may occur, with loss of polarity of epithelial cells and intraepithelial lymphocytosis alone. These changes most often occur in asymptomatic serologically positive patients and family members, particularly first-degree relatives with few or no symptoms. These may also be observed with the closely linked disorder, dermatitis herpetiformis. With a 'moderate lesion,' definitive changes in the structure of the villi are also evident.

Changes in celiac disease also develop along the length of the small intestine. The extent of these inflammatory changes appears to correlate with the severity of the clinical presentation. In classical celiac disease with diarrhea and weight loss, severe biopsy changes may extend well into the jejunum, while only limited changes are present distally in the ileum. Some clinicians have hypothesized that this 'proximal-to-distal' gradient in the severity of histopathological changes is reflective of higher concentrations of dietary gluten (or the offending peptides) in the proximal small intestine. Other 'indirect' effects may result elsewhere in the gastrointestinal tract, including the gastric and colonic mucosa, due to the immune-mediated effects of recirculating memory T cells. Even though the ileum may be virtually normal, prior classical studies using infused peptide solutions through long intestinal tubes demonstrated that the ileum is very sensitive to infused gluten peptides. With more extensive involvement of the small bowel, diarrhea and malabsorption of numerous macro- and micronutrients may occur. In contrast, if the changes are limited to the most proximal small bowel, such as the duodenum, diarrhea and weight loss may not be present. In some, isolated iron deficiency may develop, due in part to localization of most significant pathological effects of celiac disease in the duodenum, the main site of absorption of iron (as well as other nutrients) (Freeman, 2015b).

Administration of a gluten-free diet usually results in resolution of diarrhea and weight gain. Normalization of serological studies may also occur, even though mucosal histopathological changes may still be present. Biopsies also improve, initially in more distal sites of small-bowel involvement and eventually in the proximal small bowel. Prolonged gluten restriction may be needed, however, to define histological improvement, particularly in biopsies from the most proximal small intestine (Freeman, 2017a).

Subclinical disease

This category of celiac disease occurs in at least two distinct forms: occult disease and latent disease. Although genetically susceptible, most patients appear for the first time in their adult years with the disease. It is conceivable that some had full-blown disease from childhood and simply were not recognized, but more likely, some other environmental factor precipitated the disease. For example, the disorder may occur after an infection, usually a viral form of gastroenteritis (e.g., adenovirus and rotavirus). Here, it has been hypothesized that the mechanism for mucosal injury is due to a form of molecular mimicry that plays a role after an initial viral infection in a genetically predisposed individual. A viral peptide sequence might lead to activation of the immune system by consumption of gluten-containing grains having a similar peptide sequence.

In some with subclinical disease that is clinically occult, mucosal involvement may be limited to the most proximal small intestine, and isolated deficiencies of some nutrients (e.g., iron, calcium, and folic acid) may occur without diarrhea or weight loss. Malabsorption of other nutrients is absent because there is more than enough small intestine present. Others with occult intestinal disease may have prominent extraintestinal clinical features, for example skin disorders, dermatitis herpetiformis, or other autoimmune endocrine disorders, such as autoimmune thyroid disease, pituitary disease, or insulin-dependent diabetes (Freeman, 2016a). Some patients may initially present with a malignancy such as a lymphoma or small-bowel carcinoma, and biopsy evidence of celiac disease is detected only later (Freeman, 2009). Other intestinal disorders may be associated with celiac disease, including microscopic forms of colitis or gastritis, including collagenous colitis or collagenous gastritis. In all of these disorders, a predominance of intraepithelial lymphocytes is a key pathological element (Freeman, 2005).

Latent celiac disease is also a subclinical form of celiac disease, first documented in patients with dermatitis herpetiformis or intestinal lymphoma. Although most with dermatitis herpetiformis have a gluten-sensitive small-bowel disorder fulfilling the diagnostic criteria for a diagnosis of celiac disease, some appear to have limited or minimal small-intestinal biopsy changes. In others, the biopsies are normal. In these patients, typical changes of variable severity were induced with a high-gluten diet, demonstrating that the mucosa was gluten sensitive. In both disorders, these gluten-induced changes were then improved with a gluten-free diet.

Other causes of sprue-like biopsy changes

Other disorders may cause severe or variably severe changes in the small-intestinal biopsy and lead to diarrhea and weight loss. However, only celiac disease responds to a strict gluten-free diet (Tables 2 and 3). Some studies, particularly in children, have suggested that oats may be safely consumed by some with documented celiac disease, at least in small amounts, but oats may also be contaminated before consumption by other grains (e.g., during processing). In addition, a specific oats-induced enteropathy has been documented with histopathological changes that mimic celiac disease. Given this concern, many adults with celiac disease elect to also restrict oats from their diet.

Several other disorders may have a similar clinical and pathological appearance to celiac disease. For example, different infectious agents may produce a spectrum of histological changes, including severe and extensive changes typical of celiac disease. In adults, these changes may also be variable in severity and patchy in distribution. Usually, these are temporary, appear to respond to antibiotics, and develop more often in adults than children. Some may be due to an undetected viral agent or bacterial agent that has spontaneously resolved even without antimicrobial agents. With giardiasis, due to the protozoan agent *Giardia lamblia*, for example, a wide spectrum of pathological alteration may be present. Up to 15% may have changes that are so abnormal that celiac disease may be erroneously diagnosed, until, of course, the typical organisms are recognized in fecal material, small-intestinal fluid

Table 2 Classification of sprue syndromes.

<i>Disorder</i>	<i>Treatment</i>
Celiac disease ^a (classical, occult, and latent)	Gluten-free diet
Oats-induced villous atrophy	Oats restriction
Refractory sprue (refractory celiac disease)	Not known
Collagenous sprue (collagenous enteritis and enterocolitis)	Not known
Mesenteric lymph node cavitation syndrome	Not known
Other protein-induced mucosal injury (e.g., soy and milk)	Delete protein
Unclassified sprue (sprue-like intestinal disease)	Not known

Each of these may cause severe ('flat') or variably severe biopsy lesions. Refractory celiac disease requires evidence of an initial gluten-free diet response. In unclassified sprue or sprue-like intestinal disease, no response to a gluten-free diet could be defined.

^aCeliac disease has also been termed 'celiac sprue' or 'gluten-sensitive enteropathy.'

Table 3 Causes of sprue-like biopsy changes.

Disorder	Treatment
<i>Infectious disorders</i>	
Infections (e.g., parasite, protozoan, and mycobacteria)	Treat specific agent
Tropical sprue	Antibiotics and folic acid
Stasis syndrome (contaminated bowel syndrome)	Antibiotics
Whipple's disease (due to <i>Tropheryma whipplei</i>)	Antibiotics
<i>Deficiency syndromes</i>	
Nutrients (zinc, vitamin B12, and folic acid)	Replace specific agent
Malnutrition (including kwashiorkor)	Adequate diet protein
Immune deficiency syndromes (transplant, HIV, and congenital)	No specific treatment
<i>Others</i>	
Intestinal lymphangiectasia	Not known
Crohn's disease (with duodenal involvement)	No cause known
Graft-versus-host disease	Treat graft rejection
Immunoproliferative disease (lymphoma)	Often chemotherapy
Macroglobulinemia	Often chemotherapy
Zollinger–Ellison syndrome (with high luminal acid)	Antisecretory therapy
Drug-induced small-bowel injury (see Table 4)	Remove drug

Adapted from information originally published in 2008. Freeman HJ (2008) Pearls and pitfalls in the diagnosis of adult celiac disease. *Canadian Journal of Gastroenterology* 22: 273–280 and reproduced with permission.

aspirates, or even the biopsy per se. Other protozoan agents that can cause severe or variably severe changes in the small-intestinal mucosal architecture include *Isospora belli*, *Cryptosporidium parvum*, *Cyclospora cayetanensis*, and microsporidians, including *Enterocytozoon bieneusi*. In the acquired immune deficiency states that follow either transplantation or retroviral infection (e.g., HIV), a severe enteropathy may occur. The precise cause of the biopsy changes may be difficult to determine in this setting because of the propensity for other concomitant infectious agents. Sometimes, multiple agents may be present. In HIV infection causing AIDS, it has been speculated that the retroviral agent may be directly responsible, or, alternatively, that an immunologic dysfunction indirectly results. These changes may be associated with superimposed malnutrition or other infectious agent(s) to cause the small-intestinal pathological changes. *Mycobacterium avium-intracellulare* infection frequently occurs in AIDS and forms a distinctive pathological lesion with severely altered architecture. Foamy macrophages, located mainly in the lamina propria region, positively stain for acid-fast organisms. These also develop a positive staining reaction with the periodic acid–Schiff reagent, reminiscent of the staining pattern in Whipple's disease. However, with the latter disorder, now recognized to be caused by Whipple's bacillus (i.e., *Tropheryma whipplei*), acid-fast stains are negative. Parasites may also cause severe but patchy or variable changes, and some may be morphologically identified in the same biopsy specimen or fecal material (e.g., *Strongyloides stercoralis*, hookworm, and *Schistosoma* or *Capillaria* species). Some viral agents (e.g., cytomegalovirus) may be seen in the small intestine, often in patients with a compromised immune system. Bacterial overgrowth, or a contaminated small-bowel syndrome, may also be superimposed on celiac disease, and some have suggested that an empirical course of a broad-spectrum antibiotic may be sufficient to resolve changes.

Other disorders may cause diarrhea with or without malabsorption and may cause severe changes in small-intestinal biopsy architecture. Distinctive pathognomonic changes may be detected with lymphangiectasia, macroglobulinemia, abetalipoproteinemia, amyloidosis, lipid storage disorders, and radiation injury. In addition, some medications may cause sprue-like small-intestinal mucosal changes, but respond completely to removal of the offending agent (Table 4). One medication that is no longer available

Table 4 Drug-induced sprue-like small-bowel disease^a.

Drug class	Example
Nonsteroidal anti-inflammatory drugs (NSAIDs)	Sulindac
Immunosuppressives	Azathioprine
Antimicrobials	Neomycin
Chemotherapeutic agents	Busulfan
Vinca alkaloids ^b	Vincristine
Antimetabolites	Methotrexate
Angiotensin II receptor antagonists	Olmesartan

^aDrugs listed are agents that may cause a small bowel lesion that may mimic untreated celiac disease.

Removal of the offending agents results in resolution of small intestinal changes (Freeman, 2014).

^bVincristine also induces a small-intestinal enteropathy with some features of celiac disease; however, it may be distinguished by its stathmokinetic effects, causing prominent metaphase arrest from mitotic blockade.

for clinical use, triparanol, was previously used to create changes similar to those of celiac disease for research purposes. The precise mechanism for these drug-induced changes is not known.

Olmesartan enteropathy has not only been shown to histologically mimic both celiac disease (Freeman, 2016b), but also the closely associated small bowel mucosal disorder, collagenous sprue (Freeman, 2020).

Crohn’s disease may cause duodenal mucosal granulomas, but severe architectural changes without granulomas, indistinguishable from untreated celiac disease, may also occur in the proximal small intestine. In Crohn’s disease, these changes do not improve with a gluten-free diet.

Another more recently recorded entity is an unusual and relatively distinctive diffuse proximal small-intestinal enteritis that occurs rarely in patients following colectomy for extensive ulcerative colitis or Crohn’s colitis (Freeman, 2019). In these, a gluten-free diet has no effect, and, occasionally, powerful immune suppression with high-dose corticosteroids or a calcineurin inhibitor is needed.

Refractory celiac disease

In celiac disease, diarrhea or malabsorption may recur. Although the mucosa may initially respond to a gluten-free diet, severe or moderately severe histopathological changes may recur. A broad array of possible causes should be considered (Table 5). Most commonly, gluten is being consumed. This may be due to an intentional failure of compliance, or it may be completely unintentional and unrecognized. Gluten is found in many ingested sources, including pill capsules and communion wafers. There may also be a difference in tolerance to gluten among patients, with a minimum threshold in some patients.

In some with celiac disease, an unrecognized infectious cause may be superimposed. Alternatively, celiac disease may predispose to a nutrient deficiency that may cause pathological changes per se. Folic acid deficiency or zinc deficiency may cause independent histopathological changes that may be difficult, in themselves, to confidentially differentiate from celiac disease alone. In patients with long-standing celiac disease, pancreatic exocrine insufficiency may be superimposed, especially if there is concomitant malnutrition. In others, the original diagnosis may have been incorrect. Documentation of a response to a gluten-free diet is critical, since the biopsy alone is not diagnostic. In Crohn’s disease with involvement of the duodenum, for example, pathological changes fail to respond to a gluten-free diet (Freeman, 2008).

Occasional cases of celiac disease appear to be complicated by other disorders, such as collagenous sprue (Freeman, 2005). This is a rare entity and may be detected without a definite background of celiac disease. Usually, there are features of severe pan malabsorption of multiple nutrients. Biopsies reveal a pathologically distinctive subepithelial band of collagen that may be demonstrable with histochemical staining reactions (e.g., trichrome) and electron microscopy showing the typical 640A bandwidths of collagen fibers. Long-term parenteral nutrition support may be needed. Free perforation of the small intestine or lymphoma has been recorded in collagenous sprue. Another descriptive entity has been recorded that complicates celiac disease with recurrent pathological changes of variable severity, splenic hypofunction, and cavitation of mesenteric lymph nodes. In this disorder, lymphoma has been recorded.

Lymphoma, and very rarely other malignancies (e.g., small-bowel adenocarcinoma), may complicate celiac disease. Both B-cell and T-cell types have been described in celiac disease. In tertiary care centers, an overall rate of 8–10% has been recorded, but, in recent years, the lymphoma risk appears to be falling, in part possibly because serological screening studies have increased the detection rate for celiac disease in those with limited symptoms. Age at the time of the initial diagnosis of celiac disease may be a critical factor. If celiac disease is initially diagnosed late in life, lymphoma may occur more often. Duration of the disease prior to initiation of a gluten-free diet may be important. Most often, lymphoma develops in the jejunum, but localization in the ileum can occur. Colonic and gastric lymphomas have also been described. Usually, lymphomas produce an ulcerating or stenosing and obstructing tumor. Rarely, lymphoma may be diffuse and multifocal with only mucosal localization. If erosions or ulceration are present in the small intestine, particularly the duodenum, lymphoma may be exceedingly difficult to diagnose; Crohn’s ulceration or so-called ulcerative jejunoileitis may be recorded. In some of these, only later, frankly neoplastic lymphoma cells may be detected that were previously difficult to appreciate in an inflamed small intestine. Free perforation of the small intestine may be due to a

Table 5 Causes of refractory celiac diseasea.

Limited gluten-free diet compliance ^a
Unrecognized source of dietary gluten
Superimposed cause (e.g., folic acid or zinc deficiency)
Second cause for symptoms (e.g., infectious diarrhea)
Wrong initial diagnosis (e.g., Crohn’s disease involving the duodenum)
Associated disease (e.g., collagenous sprue or collagenous colitis)
Complicating disease (e.g., lymphoma, specifically T-cell enteropathy)

^aFailure to respond initially to a gluten-free diet suggests ‘sprue-like’ intestinal disease or unclassified sprue, not refractory celiac disease.

lymphoma, and it should be suspected if celiac disease is known to be present. Diagnosis of lymphoma may be challenging. In some, full-thickness biopsies may be needed, or evaluation using flow cytometry, special immunohistochemical studies, or polymerase chain reaction.

Sprue-like intestinal disease or unclassified sprue

This refers to a severe ('flat') or variably severe (moderate to mild) mucosal lesion that has not responded to a gluten-free diet. Although some with this entity have been labeled as having 'refractory celiac disease,' a response to a gluten-free diet has not been documented. Usually, repeated biopsies have been abnormal despite a gluten-free diet. Most continue to have symptoms and fail to show any clinical response to a gluten-free diet. In some, dietary compliance may be difficult to prove and histological improvement may be difficult to document, especially with duodenal biopsies alone. This may represent a heterogeneous group of small-bowel disorders, a 'wastebasket group' with no definitive cause. It has been speculated that some may have a 'resistant form' of celiac disease, while others may have a 'difficult-to-diagnose' lymphoma. In some, an abnormal subset of intraepithelial lymphocytes has been described, suggesting an important prognostic marker for later lymphoma development.

Genetics

Celiac disease is a heterogeneous disorder, reflected not only by its differing clinical presentations but also pathologically with different degrees of architectural change and variable extents of inflammatory change along the length of the small intestine. Some serologically positive patients may have architecturally normal small-intestinal mucosa, although minimal changes with only a slight increase in the number of intraepithelial lymphocytes may be evident. Recent studies have reported that immunohistochemical evidence of immune activation alone may be present. Traditionally, a gluten-free diet has not been recommended if only an architecturally normal small intestine is present, but increasingly sophisticated immunochemical or other laboratory methods may eventually result in an expanded definition of the limits of 'normal' requiring more intense clinical monitoring.

It has been estimated that approximately 40% of the heritability of celiac disease can be explained on the basis of the human leukocyte antigen heterodimers, HLA-DQ2 and HLA-DQ8. These are believed to be necessary to develop celiac disease, but they are not, in themselves, sufficient for phenotypic expression of the disease. Other non-HLA genes may also be involved. One may relate to genetic variants on chromosome 19, in the myosin IXB gene (i.e., MYO9B), and may potentially predict the responsiveness of celiac disease to a gluten-free diet. Other genetic studies have identified a total of nine non-HLA loci that contribute to celiac disease risk (Gujral et al., 2012).

Celiac disease-associated HLA-DQ molecules serve to bind and present gluten peptides to antigen-specific T cells in the intestinal mucosa. These induce T-cell proliferation and cytokine secretion. Siblings with shared HLA haplotypes have a greater likelihood of concordance with celiac disease than those without shared haplotypes. It has also been hypothesized that specific genetic markers might have value in predicting the clinical course of disease. For example, two copies of DQB1*02 have been associated with a greater disease risk, but they were not predictive of an earlier age of onset or the severity of the disease. Finally, in twin studies, with one twin being biopsy defined, the cumulative concordance in the second twin was almost 80% for symptomatic or 'silent' forms of celiac disease within 5 years.

Pathogenesis

Gliadins, from an alcohol-soluble fraction of gluten, are storage proteins in wheat, barley, and rye (along with other gluten-containing grains). All gliadins have a high glutamine and proline content. Glutenins are insoluble in alcohol and differ in their biochemical structure from gliadins. It has been hypothesized that the initial immune reaction in celiac disease patients is focused on several of these gliadin peptides, while the long-standing inflammatory response may be defined by gliadin peptides that have been deamidated or cross-linked by tissue transglutaminase. These latter peptides are also more tightly linked to HLA-DQ2 and HLA-DQ8 (Gujral et al., 2012).

The tissue transglutaminase-catalyzed changes in gliadin are not restricted to single gliadin types. For example, prolamines in barley and rye are known as hordelin and secalin, respectively, and these may induce a messenger RNA-mediated interferon-gamma response in the small-intestinal mucosa of celiacs. An alpha-2-gliadin-33-mer appears to pass through the enterocyte brush border membrane by a dose-dependent translocation mechanism, and this is further enhanced by interferon-gamma, possibly mediated by a delayed epidermal growth factor endocytosis. In active celiac disease, this immune-mediated response is very complex and involves many different mediators that are still being studied. For example, a marked accumulation of specific Th-1 immune cells occurs that produces interferon-gamma. A number of other transcription factors and other mediators (e.g., interleukin-21) may be increased in celiac disease. Interleukin-21 is a key regulator, being present in activated CD4 + T cells as well as in natural killer T cells, and these cells, in turn, regulate the production of cytokines by different T-cell subsets.

With genetic susceptibility, gliadin may interact with enterocyte tight junctions and cause their disassembly. Gliadin peptides may bind to the chemokine receptor, CXCR3. This induces zonulin release from the tight junction region and causes a

resultant increase in intestinal permeability. Permeability increases have also been demonstrated prior to the onset of clinically apparent celiac disease, and even with a gluten-free diet, this altered tight junction permeability may not completely return to normal (Gujral et al., 2012).

Another important central or superimposed component to the pathogenesis of celiac disease may involve the luminal intestinal microflora. It has been hypothesized that these normally present resident intestinal microbes may play a critical role in the expression of the disease. Alternatively, it has been suggested that some infectious agents may actually have contributed to a Swedish childhood epidemic of celiac disease. These infectious agents, however, may not be restricted to the luminal microbiome, but instead the luminal virome. In a recent report, reovirus, a normally innocuous viral agent, was observed to trigger inflammatory responses to dietary antigens and development of celiac disease (Bouziat et al., 2017).

Treatment

At present, the treatment of celiac disease remains a lifelong gluten-free diet. However, the definition of a gluten-free diet may differ from one nation to another. The World Health Organization has proposed that gluten-free foods should not contain more than 200 ppm of gluten. Each individual celiac, however, may also have a unique genetically determined threshold or tolerance to dietary gluten. It is believed that a daily intake of less than 10 mg will not cause significant histological changes in the small intestine of celiac disease patients. A continuing difficulty in management relates to monitoring of compliance with a gluten-free diet. For most who adhere to a gluten-free diet, intestinal symptoms resolve, serological parameters normalize, but biopsies, especially if obtained only from the most proximal small intestine, may take prolonged periods to improve, sometimes months or years (Freeman, 2017a, b). It appears that normalization of the biopsy changes also requires longer periods in elderly celiacs, especially if the disease was initially diagnosed late in life.

Most celiacs who carefully follow their gluten-free diets respond well to the diet alone; however, there may be a role in some individuals for added supplementation with micronutrients. For example, a recent double-blind placebo controlled clinical trial demonstrated that supplementation with vitamin B provided significant improvement in general well-being. In others, iron, folic acid, zinc, and calcium supplements may be considered.

Gluten-free products are costly and difficult to readily obtain in some countries. As such, a number of alternatives to the gluten-free diet are being investigated. To date, none have been recommended as a sole treatment strategy. Some in clinical trials, or considered in a discovery phase, have included orally administered enzymes (e.g., endopeptidases), antagonists to S100B protein, interleukin-15 blockers, elemental diets, and transamidation of wheat flour. Lactobacilli, added to sourdough for fermentation, may also serve to hydrolyze the proline- and glutamine-rich gluten peptide (Gujral et al., 2012).

Oral prolyl-endopeptidases may digest ingested gluten and, theoretically, might represent a new approach to treatment for celiac disease. These proteases may be derived from different bacterial sources and function by reducing the quantity of immunostimulatory gliadin peptides present in the small-intestinal lumen. Other approaches include the modification of gluten proteins to eliminate their capacity to stimulate interferon-gamma release from CD4 + T cells or, alternatively, impair gluten-reactive T cells through an immunotherapeutic method, such as vaccination. Polymeric binders examined using in vitro model systems and in transgenic mice have been shown to reduce the deleterious effects of gliadin on the intestinal epithelial cells.

Another focus has been to alter the action of antigen presenting cells, particularly a unique subset of dendritic cells responsible for local activation of gluten-reactive T cells in celiac disease. Enteric glial cells have been shown to release neurotropic factors and appear to be activated by inflammatory insults. A protein released from these cells in the duodenum, S100B protein, is reduced on a gluten-free diet and may be a useful product that can be used to interfere with the usual immune response.

Finally, another investigative area has focused on intestinal permeability changes that may be increased in celiac disease associated with altered tight junction proteins, specifically zonulin. AT-1001 is an inhibitor of paracellular permeability and reduced increased permeability in celiac disease challenged with gluten. AT-1001 was also shown to diminish the anticipated rise in interferon-gamma levels with gluten feeding and so may have significant theoretical potential for treatment of celiac disease.

Conclusion

Celiac disease is an immune-mediated small-intestinal mucosal disorder associated with intolerance to gluten peptides in genetically predisposed individuals. Although the disorder classically causes diarrhea, malabsorption, and weight loss, it may also be associated with other autoimmune disorders and suspected with serological screening. The disease affects 0.5–2% of populations in some nations examined to date, but the most significant risk factor is established celiac disease in an immediate family member, particularly a sibling. Definition of the disease includes an intestinal biopsy before treatment with a gluten-free diet along with documentation of a response to a gluten-free diet. Serological testing may provide added evidence that celiac disease is present and may potentially be useful for monitoring gluten-free diet compliance. The disorder has a complex pathogenesis that may ultimately lead to alternative forms of treatment.

EDITOR-IN-CHIEF

Nima Rezaei gained his medical degree (MD) from Tehran University of Medical Sciences and subsequently obtained an MSc in molecular and genetic medicine and a PhD in clinical immunology and human genetics from the University of Sheffield, UK. He also spent a short-term fellowship of pediatric clinical immunology and bone marrow transplantation in the Newcastle General Hospital. Professor Rezaei is now the full professor of immunology and vice dean of International Affairs, School of Medicine, Tehran University of Medical Sciences, and the co-founder and head of the Research Center for Immunodeficiencies. He is also the founding president of Universal Scientific Education and Research Network (USERN). Prof. Rezaei has already been the director of more than 100 research projects and has designed and participated in several international collaborative projects. Prof. Rezaei is the editor, editorial assistant, or editorial board member of more than 40 international journals. He has edited more than 50 international books, has presented more than 500 lectures/posters in congresses/meetings, and has published more than 1100 scientific papers in the international journals.

FOREWORD

It is a great honor to be asked to introduce, with this foreword, the *Encyclopedia of Infection and Immunity*. This work will be read and enjoyed by many students, both graduate and postgraduate, including clinicians, laboratory practitioners, and scientists. Many colleagues have contributed to this important work, with over 230 original chapters assembled in sections and listed alphabetically. I offer my warm congratulations to the editors of this book, for soliciting a wide body of expertise and assembling it in a form that gives so much pleasure and information to the reader.

For those of us who work in the field of infection and immunity, the last two years have been exceptionally challenging. At the current time we are 22 months into a major pandemic caused by a novel coronavirus and its variants, and worldwide, sadly, there have been many hospitalizations and deaths. Clinicians and scientists in our field have been working flat out, caring for patients, generating or utilizing diagnostic tests, generating new knowledge in immunity to coronaviruses, or discovering, testing, and deploying new vaccines. Public Health practitioners have organized our medico-social responses to limit transmission and deal with the consequences of infection. Behavioral scientists have transformed our approach to informing the public, getting the best possible outcomes from effective communication. Governments have learned the danger of ignoring the expertise of scientists, and in many countries, the public look upon clinicians and scientists with gratitude and respect. It is a testament to the advancement of infection and immunity science that the genome of the virus was sequenced within a few weeks of COVID-19 emerging, and that within 12 months, the first trials of novel vaccines had been completed. These vaccines included some with exceptionally novel technologies, including the RNA vaccines and the viral-vectored vaccines.

Underpinning the academic agility of students and practitioners in Infection and Immunity is the universal strength of sound education. Readers of this book will be seeking the knowledge they need for a comprehensive understanding of infectious disease and immunology. We work in a fascinating discipline. Our field is unique in that pathogenesis involves at least two sets of genomes—on the one hand the microbe, and on the other, the host. The microbial genome programs its microenvironment to enable acquisition of and residence in a niche for sufficient time to replicate and further disseminate to other hosts. The human genome has evolved to tolerate and contain a wide range of symbionts and pathobionts, with highly sophisticated immune decision-making at the cellular level, but to respond to invading species with an elaborate coordinated repertoire of innate and acquired immunity. The complex conversation between many different microbes and the human host generates a wide range of disease phenotypes. This makes the job of an infectious disease physician so challenging but at the same time so fulfilling.

Our field is enriched by the many scientists and clinicians who are willing to share their experience with their peers and students. This book reflects the great variety of knowledge that has emerged over centuries of inquiry and endeavor, and I believe you will be rewarded by using it as one of your reference sources.

Robert C. Read

Editor-in-Chief, Journal of Infection

Professor of Infectious Diseases and Consultant Physician

University Hospital Southampton, United Kingdom

PREFACE

Although infections have been one of the most important health threats since centuries ago, the mechanisms of human defense against infections have been unclear until last century. The scientific world has remarkable progresses in the field of immunology during recent decades. Indeed, the novel discovery of genes related to different pathogens has enhanced our knowledge about the immune system. Understanding different pathogens and the immune mechanisms promote diagnostic strategies and design more efficient therapeutic agents.

Encyclopedia of Infection and Immunity is a comprehensive text, which covers topics not only on basic immunology and microbiology but also on clinical immunology and infectious diseases. Section 1 focuses on the immune system, while Section 2 describes the interaction between pathogens and immunity. Bacteria, viruses, fungi, protozoan parasites and helminths, and insect and mites are explained in Sections 3–6, respectively. Section 7 discusses the clinical infectious disease challenges, whereas clinical immunology is covered in Section 8. Laboratory tests and treatment protocols are the main focuses of Sections 9 and 10, respectively.

Encyclopedia of Infection and Immunity is the result of valuable contribution of more than 400 scientists from many well-known universities/institutes worldwide. I would like to hereby acknowledge the expertise of all contributors, for generously devoting their time and considerable effort in preparing their respective chapters. I would also like to express my gratitude to Elsevier for providing us the opportunity to publish this Encyclopedia.

Finally, I hope that this comprehensive book will be of special value for researchers and clinicians who wish to extend their knowledge on infection and immunity.

Nima Rezaei, MD, PhD

CONTENTS OF VOLUME 4

Section 9: Laboratory Tests, Edited by Nima Rezaei

Introduction on Laboratory Tests for Diagnosis of Infectious Diseases and Immunological Disorders <i>Mona Sadeghalvad and Nima Rezaei</i>	1
Laboratory Identification of Bacterial Infections <i>J Michael Janda</i>	19
Laboratory Identification of Fungal Infections <i>María Mercedes Panizo and Xiomara Moreno</i>	34
Laboratory Identification of Prion Infections <i>Hasier Eraña, Jorge M Charco, Miguel A Pérez-Castro, Carlos M Díaz-Domínguez, Cristina Sampedro-Torres-Quevedo, Izaro Kortazar-Zubizarreta, Leire Fernández-Veiga, Juan Tasis-Galarza, and Joaquín Castilla</i>	63
Microbes Culture Methods <i>Md Latiful Bari and Sabina Yeasmin</i>	77
Antibody Tests <i>Janet M Daly</i>	99
Flowcytometric Assessment of B Cell Development and Functional Assays on B Cell Development <i>Ugur Kalan</i>	106
Functional Assessment of T Cells <i>Charalampos D Moschopoulos, Thilo Berger, and Chrysanthi Skevaki</i>	122
Phagocytosis: Biology and Methods <i>Adebayo J Molehin, Jacob Nichols, Flint Smith, and Kenneth Nugent</i>	134
Neutrophil Function Assays <i>Iraia Ladero-Auñon and Natalia Elguezabal</i>	141
NK Cell Function Analysis <i>Jacek M Witkowski and Tamas Fülöp</i>	153
Complement Assays <i>Anete Sevciovic Grumach and Michael Kirschfink</i>	161
Functional Testing of the IL-12/IFN- γ Circuit <i>Laia Alsina, Ana Esteve-Sole, Carlos Rodríguez-Gallego, and Alexandru Vlaga</i>	167
Interferon Signature Analysis <i>Newman Osafo and Silvio Owusu Dei</i>	181

Introduction

Laboratory tests are extremely valuable in validating a diagnosis, predicting disease severity, and also in following up on the disease activity in patients who are suspected of having infectious diseases or immunological disorders. Diagnostic reliability and health benefits could be considered as two important factors when testing for such diseases. Meanwhile, timely diagnostic assessment and implementation of accurate tests are highly valuable in disease management (Caliendo, 2013). Microbiological methods, including culture and staining, have previously become the gold standard for detecting infectious diseases. These techniques can directly detect microorganisms such as bacterial, viral, parasitic, or fungal agents in fluids or tissues of the patient. Although these tests are reliable, characteristics such as time-consuming testing hamper quick diagnosis (Laupland and Valiquette, 2013). Currently, utilizing indirect laboratory techniques to evaluate infectious diseases is of utmost importance for detecting specific antibodies or pathogen antigens in blood or body fluids. Several laboratory methods have been designed for detecting either pathogens or specific antibodies in the suspected subjects. Pathogen isolation and serological methods are the conventional diagnostic tests that are widely applied to recognize the cause of a disease (Amar, 2014). Furthermore, molecular diagnostics became an important tool in healthcare in the early 1990s, when specific monoclonal antibody technology was developed. Molecular tests have higher sensitivity

and specificity compared to traditional methods. These methods can be helpful in the surveillance and control of infectious diseases, but more precise and sensitive diagnostic methods are still required (Lu et al., 2020). In this article, we will review the most important laboratory tests that are widely used to diagnose infectious diseases or various immunological disorders, including autoimmune and immunodeficiency disorders.

Diagnostic laboratory tests: Focusing on infectious diseases

Direct detection of microorganisms: Culture, staining, microscopy

Culture is usually the gold standard for identifying organisms, but results can take days or weeks. Furthermore, because culture cannot be performed for all infections, alternative tests are required. Following culture and identifying the organism, evaluation of the pathogen's susceptibility to antimicrobial drugs can also be performed. This can be helpful in implementing the appropriate antimicrobial therapy. Molecular methods can also be used to find particular resistance genes.

In order to identify a pathogen and microscopic detection, different staining methods can be used. Gram staining (using crystal violet dye) is frequently used in microbiology laboratories to classify bacteria into gram-positive or gram-negative and to characterize bacteria morphology (e.g., cocci, bacilli) (Srinivasan et al., 2012). Another staining method known as acid-fast staining (or Ziehl-Neelsen staining) is used to identify mycobacterium species. Carbol fuchsin is used in acid-fast staining that can dissolve the lipid components of the Mycobacteria cell wall. Using heat allows further penetration and therefore dye entrance into the cytoplasm. As a result, all cells appear red. Acid fast cells remain red following the decolorization step, while non-acid fast organisms become colorless. So, the colorless cells appear blue following staining with methylene blue in the next step. Therefore, the red and blue colors represent acid-fast and non-acid fast bacteria, respectively (Lamanna, 1946).

Serological methods: Assay based on antigen-antibody reaction

"Max von Gruber" was the first to use serologic methods to diagnose infectious agents (Von Gruber and Durham, 1896). He used sera from infected animals and humans to agglutinate typhus and cholera bacteria. The invention of the complement fixation procedure by "Bordet and Gengou" in 1901 is also regarded as another milestone in detecting infectious agents through serologic methods (Silverstein, 2009). Serologic tests are simple and inexpensive methods that provide immediate results. Serologic tests for infectious diseases can provide information about the disease even when there is no virus or its components in the sample. In addition, these tests can also confirm the presence of infection in asymptotically infectious diseases (Vainionpää et al., 2015).

In general, serologic tests are based on the specific interaction between antigen and antibody. Antigens can be a part of a pathogen like bacteria and viruses or a non-pathogenic agent such as red blood cells (RBC), hormones, tissue proteins, etc. Binding of antigen to an antibody is a specific reaction that can be influenced by several factors such as the pH of the environment (optimum pH is approximately 7.2), ionic strength, concentration ratio of antigens and antibodies, environment's temperature, and incubation time (Vainionpää et al., 2015). Optimal reaction between antigen and antibody and forming antigen-antibody complexes can occur in the appropriate condition. Importantly, the higher or lower concentration of either antibody or antigen causes false negative results. Higher concentrations of antibodies, for example, in a variety of tests such as Wright and Widal (serologic tests for the detection of Brucellosis and typhoid, respectively), can result in a phenomenon known as the "Prozone effect," in which the ability of antibodies to form immune complexes is impaired. Similarly, the excess concentration of antigens in tests such as CRP-latex (for detection of C-reactive protein in the serum) can result in the "Postzone effect" causing inappropriate formation of antigen-antibody complexes (Jin and Zehnder, 2016).

Serological diagnosis is generally based on the production of specific antibodies in the sera or other body fluids. IgM is the first class of antibody produced and peaks at 7–10 days following the disease occurrence, and then begins to decrease. The IgG antibody is then produced and persists for a long time after infection, facilitating the detection of infection. Therefore, an increase in IgG antibody titer over a period of about 4 weeks can usually be a sign of infection. For this reason, taking two samples from the patient at intervals of 1–4 weeks will usually be valuable in diagnosing the disease through serological tests (Vainionpää et al., 2015). Although these tests are very useful, they also have disadvantages or limitations. In certain infections, the antibody response is insufficient, or the antigens used in the test have a limited specificity, making the findings difficult to interpret. The serological response in immunocompromised patients is often too weak. In neonatal infections, the presence of maternal antibodies may make it difficult to demonstrate a response in the infant. Therefore, other diagnostic procedures should be performed in these contexts.

There are various types of serological tests that can detect antibodies or antigens in a sample. These tests can be categorized based on the following properties:

- 1) Antigen nature: including agglutination tests, precipitation tests, flocculation tests.
- 2) The function of antibodies: including neutralization test, complement fixation, hemolysis-based tests.
- 3) Labeling techniques: including ELISA, IFA, RIA, CLIA.
- 4) Blotting test: including western blotting.

In the following part we will review these tests with more details.

Agglutination tests

Agglutination occurs when an insoluble or particle antigen interacts with an antibody. A positive reaction can be detected macroscopically in a short time. However, the antigen-antibody complex may be seen with the naked eye if the complex size is large. Both IgG or IgM could be involved in the agglutination reaction. So, this test is not appropriate for distinguishing between these two classes of antibodies (Smits et al., 2000). Agglutination reactions can be divided into three categories based on the nature of antigenic determinants in antigen molecules (Oss, 2000).

- 1) Direct (active) agglutination: in this reaction, the antigenic determinants are the intrinsic component of an insoluble (or particle) antigen (Fig. 1A). For example, in bacterial agglutination assays such as the Wright and Widal tests, killed *Brucella* and *Salmonella* bacteria used to diagnose Brucellosis and Typhoid (enteric fever), respectively. In fact, in this test, dead or inactivated bacteria suspensions are used as antigens. In this test, a dilution series of the patient's serum is incubated with a defined antigen suspension. This could be done in tubes, microscope slides, or microtiter plates. A positive reaction occurs when antibodies are present in the serum. Other examples include the hemagglutination assay for identifying blood groups and the Paul Bunnell reaction for diagnosing infectious mononucleosis (Kim et al., 2015; Park et al., 2012; Tilton et al., 1988).
- 2) Indirect (passive) agglutination: in this type of agglutination, the antigen is soluble (not a particle) that binds to insoluble particles such as polystyrene latex, gelatin particles, or erythrocytes (Fig. 1B). Examples include the RA-latex test for detecting rheumatoid factor in the serum. Antibody (IgG) against rheumatoid factor is bound to a latex particle to detect rheumatoid factor in the patient's serum. Rheumatoid factor is mostly a pentameric IgM, which is found in the serum of patients with rheumatoid arthritis. The principle of the CRP-latex test is also based on indirect agglutination in which anti-CRP antibodies are attached to the latex particles. Therefore, the presence of C-reactive protein (CRP) in the patient's serum leads to a positive test (Chandra et al., 2014; Plotz and Singer, 1956).

Another example is the pregnancy test through the detection of human chorionic gonadotropin (hCG) in the urine (Fig. 1C). This test is based on agglutination inhibition, in which two forms of antigen, soluble and insoluble, compete for a specific antibody. hCG, a hormone produced during pregnancy, is a "soluble" protein and can be detected in serum or urine for pregnancy diagnosis. In this test, suspected urine is firstly mixed with specific anti-hCG antibodies. Subsequently, the latex particles coated with hCG (hCG-latex) are added to this mixture. If hCG is absent in the urine, the specific antibodies against the hormone remain free, and later, when hCG-latex particles are added, these antibodies form a complex with hCG-latex and therefore agglutination can occur. Therefore, if agglutination is observed, the test is negative. On the other hand, if hCG is present in the urine, it first binds to specific antibodies but their complex is not visible and cannot be detected because of the solubility of hCG hormone. The hCG-latex particles that are added to this complex in the next step remain free due to the lack of specific antibodies against them and therefore agglutination does not occur (Santomauro and Sciarra, 1967).

Fig. 1 Three types of agglutination tests. (A) Direct agglutination: interaction between particle (insoluble) antigen and antibodies results in the formation of large agglutinated particles which can be observed with the naked eye or by a microscope; (B) In the indirect agglutination method, soluble antigens are bound to an insoluble particle such as latex to make the reaction visible; (C) In the agglutination inhibition test, such as detection of hCG in the urine (in a pregnancy test), soluble and insoluble antigens are competing for binding to antibodies. In a pregnant person, soluble hCG in the urine binds to the anti-hCG antibodies in the first step. But, this reaction cannot be seen because of the solubility of the formed immune complexes. hCG coated latex is added in the next step. Since antibodies are bound to urine's hCG in the first step, therefore, no free antibodies remain to react with hCG-coated latex particles. As a result, the outcome of agglutination is negative. In contrast, the lack of hCG in the urine of a non-pregnant person causes the antibodies to remain free in the first step. Therefore, by adding latex particles, the agglutination occurs. hCG, human chorionic gonadotropin.

Precipitation tests

Precipitation refers to serological reactions in which the antigen is soluble. These tests can be performed on a slide, in a tube, or on agar or gel for the detection of antigen or antibody. The immunodiffusion in agar gel is the most frequent test based on precipitation. Two common types of immunoprecipitation assay include single radial immunodiffusion (SRID or Mancini method), and double immunodiffusion (DID or Ouchterlony method). In DID, antigens and antibodies are placed separately in two wells punched on the agar gel. After incubation in an appropriate condition (e.g., at 25 °C for at least 24–48 h in a humidity chamber), both antigens and antibodies are diffused in the agar and may react once they interact. In SRID, one component, for example an antigen, is placed in a pre-punched well in the agar containing antibody (antibodies are dissolved in the agar before it is placed on the slide). Therefore, the precipitation lines are formed if the antigen-antibody complex is made. An amido black staining may be used to make the precipitates more visible. These tests are rapid and simple, but they are relatively insensitive and non-quantitative. However, they can be used for the detection of either antigens (e.g., viral, bacterial) or antibodies in infectious diseases (Oss, 2000).

Flocculation tests

Flocculation refers to a reaction between a colloidal antigen and an antibody resulting in the formation of flaky and coarse immune complexes. Cardioliipin antigen is an example of a colloidal antigen that is used in the VDRL test to diagnose syphilis. Cardioliipin is prepared from beef heart extraction and is used to detect syphilitic reagin in the patient's serum. In VDRL, a suspension containing cardioliipin, lecithin, and cholesterol is added to the patient's serum. If the antibody is present in the serum, it interacts with antigenic solution and the formed immune complexes are then observed simply by a microscope. VDRL can be performed on serum or CSF samples (Vogelsang and Haaland, 1951).

Neutralization tests

Neutralization tests are based on the binding of antibodies to the pathogen or to toxins, resulting in the inhibition of their biological properties. This method can be applied to detect pathogens (with defined immunosera) or their toxins or to identify antibodies (with defined pathogens). An example the anti-streptolysin O (ASO) test for detecting antibody against streptolysin O (SO) in the patient's serum produced following streptococcal infections. The ASO test can be used for diagnosing post-streptococcal sequelae such as rheumatic fever or acute glomerulonephritis. In this test, different dilutions of the serum are incubated with a defined amount of SO enzyme (commercially ready). If the anti-SO antibodies are present in the patient's serum, they bind to the SO and neutralize it. RBC is used as an indicator to determine if the enzyme is neutralized. SO has the ability to lyse the RBCs and the neutralized enzyme would not be able to lyse RBCs (Gerber et al., 1990).

Complement fixation test (CFT)

Using the complement fixation test, the antibody titer and the amount of serum complement can be measured. Complement fixation testing is a very sensitive method based on the reaction between three components: antigen, antibody and complement. This test is performed by the macro method in tubes and by the micro method microtiter plate.

In this test, animal sensitive RBCs, usually sheep's RBCs (sRBCs) bounded to an antibody against sRBC (known as hemolysin), are used as a detector. In this procedure, the own complement of the sample should be inactivated at first. Then, known antigen and complement are added to the suspected serum. If the antigen-antibody complexes are formed, the complement system binds to them and consumed. Sensitive RBCs are then added to the mixture in the next step. If the serum is positive for antibodies, the complement is consumed in the first step because of the formation of the antigen-antibody complexes. Therefore, hemolysis-mediated complement will not occur after adding erythrocytes. As a result, if hemolysis happens, the test is likely to be negative. The titer is described as the reciprocal of the sample's highest dilution that resulted in a 50% lysis in the indicator system. In general, IgM, IgG1, and IgG3 are the most important antibodies that could be detected by CFT (Vainionpää et al., 2015).

The CFT test is a very sensitive method by which at least 0.01 µg of antibody per mL of serum can be detected. The sensitivity of this method is more than agglutination and perspiration, but less than radioimmunoassay, immunofluorescence and ELISA. This test is a common method used to serologically diagnose mycoplasma pneumoniae, fungal infections such as coccidioides, histoplasma and most viruses. However, antibodies against a variety of pathogens, including the measles virus, the mumps virus, listeria, enteroviruses, Yersinia, and the rubella virus, are no longer detectable using CFT (Amanfu et al., 2000; Stern, 1965; Shepherd et al., 1986).

This test is very complicated and tedious. Important factors are involved in the CFT, including RBC count and sensitivity, the nature and amount of hemolysin to sensitize RBCs, the hemolysis activity of complement, the ionic strength and pH of the reaction environment, and incubation time.

Hemolysis-in-gel test

In this test, antigen is attached to the surface of erythrocytes that are incorporated into the gel. The patient's serum is then added to the wells punched in the gel. Subsequently, the complement is added. If the antigen-antibody complex is formed in the well, the erythrocytes will undergo lysis. This would provide a hemolytic area around the serum sample well. This test is used to detect measles antibodies in a patient's serum. The zonal diameter increases with increasing antibody concentration. The erythrocytes remain intact if no specific antibodies are present in the serum. Both IgG and IgM antibodies can be detected in a hemolysis-in-gel test. This test could be applied for screening of infectious diseases or immunity following vaccination (Wesslén, 1978).

Enzyme-linked immunosorbent assay (ELISA)

ELISA refers to immunoassay tests using enzymes. The test is based on a colorimetric assay and is usually performed on a microtiter plate. In this procedure, enzyme-conjugated antibodies are used and the enzyme can generate measurable photometric signal following adding chromogenic substrate. Different types of enzymes are commonly used in ELISA, including alkaline phosphatase (ALP), horseradish peroxidase (HRP), and β -galactosidase. ELISA has the same sensitivity as radio immune assay (RIA) but is safer and less expensive (Aydin, 2015).

A variety of ELISA tests have been established providing the quantitative or qualitative detection of antigens or antibodies, including direct, indirect, sandwich, and competitive ELISA methods (Fig. 2).

Direct ELISA is a simple method that was first developed in 1971. This method is well suited for determining the amount of antigens or antibodies. In this regard, antigens or antibodies are coated on the surface of a microtiter plate. The photometric signal can be detected following adding enzyme-conjugated antibodies and then appropriate substrate. The generated signal is directly proportional to the amount of antigen or antibody (Fig. 2A) (Engvall, 2010).

Indirect ELISA is most commonly applied in serological testing for infectious diseases or immunological disorders. In this method, specific antigens are coated in the microtiter plates for detecting specific antibodies in the patient's serum which is added in the next step (Fig. 2B). Antigen-specific antibodies (named as primary antibodies) in the serum can bind to the coated antigens if the antibodies are present in the sample. Following washing the wells, enzyme-conjugated antibodies (specific to the primary antibodies) are added. Again, after the washing step, the appropriate chromogenic substrate is added. The photometric signal resulting from this enzymatic reaction can be measured with a spectrophotometer. Indirect ELISA is frequently used to detect pathogen-specific antibodies or antibodies against certain antigens in immune disorders. The example includes identifying the

Fig. 2 Schematic diagram depicting four types of ELISA. (A) Direct ELISA; (B) Indirect ELISA; (C) Sandwich ELISA; (D) Competitive ELISA.

presence of HIV-specific antibodies in the suspected serum. For this reason, suspected serum is added to the wells of a microtiter plate coated with recombinant structural proteins of HIV (Lindström and Wager, 1978; Aydin, 2015).

Another type of ELISA technique, known as sandwich ELISA, is designed for the detection of antigens in the sample. In this method, antigen-specific antibodies (primary antibodies) are coated on a microtiter plate (Fig. 2C). By adding the unknown sample in the next step, the antigen in the sample binds to primary antibodies (if the sample is positive). Enzyme-conjugated antibodies are then added in the next step. These antibodies are specific to the primary antibodies. By adding a substrate, the photometric signal can be measured with a spectrophotometer (Kato et al., 1977).

Another procedure to assess the level of antigens or antibodies in the sample is through competitive ELISA, in which the antibodies or antigens in the patient's sample compete with a defined, enzyme-conjugated antibody or antigen over a binding site. In this method, the enzyme-conjugated antibodies are first added to the sample solution containing the antigen (Fig. 2D). This antibody-antigen mixture is then added to the antigen-coated microtiter wells. The high presence of antigen in the sample causes less free antibody to remain to bind to the coated antigens of the well. As a result, the analyte concentration has an inverse relation to the measurement signal (Yorde et al., 1976).

Another technique is designed to increase the sensitivity of the ELISA method. Enzyme-linked fluorescent assay (ELFA) is developed in which a fluorescence signal (e.g., 4-Methylumbelliferyl phosphate) is detected instead of a photometric color signal. The ELFA procedure time is quicker than ELISA and it can detect up to 10–18 mol/assay compared to ELISA that can detect only up to 10–16 mol/assay (Yolken and Stopa, 1979).

Immunofluorescence assay (IFA)

The Immunofluorescence assay can detect either antigen or pathogen-specific antibodies (Bayer et al., 2001). In this procedure, antibodies are labeled with a fluorochrome dye such as fluorescein isothiocyanate (FITC), rhodamine, and phycoerythrin. Therefore, immune complexes containing these fluorescence-labeled antibodies can be detected by colored light emitted (after being excited by light of the appropriate wavelength). The emitted light can be seen with a fluorescent microscope equipped with ultraviolet light and suitable fluorochrome filter systems. Each fluorochrome absorbs a wavelength of light and emits light at a higher wavelength. Fluorescein absorbs blue light (490 nm) and emits a fluorescent yellow-green (517 nm). Rhodamine absorbs yellow-green light (515 nm) and emits a red fluorescent dye (546 nm). Rhodamine can be used in two-color immunofluorescence tests because it emits fluorescence at a higher wavelength than fluorescein. For example, by binding fluorescein to one antibody and rhodamine to another antibody, two membrane antigens can be observed on one cell simultaneously. Phycoerythrin absorbs slightly blue-green/yellowish light (565 nm) and emits slightly orange-yellow light (573 nm) (Mullins, 2010).

Using fluorescent antibodies, the antigen or antibody of interest can be identified by a direct or indirect immunofluorescence method, respectively. Direct immunofluorescence (DIF) is a one-step histological staining procedure in which tissue antigens (fixed in a solid phase, mostly slides) can be recognized directly by adding fluorochrome-labeled antibodies. The signal is observed if the antigen-antibody complex is formed (Vainionpää et al., 2015; Aoki et al., 2010). Indirect immunofluorescence (IIF) is a two-step serological technique in which a labeled antibody is used to detect a specific antibody against an antigen in the serum. For this reason, suspected serum is added to a glass slide with antigen-coated fields, followed by adding specific labeled-antibodies. If the serum is positive for antibodies, the formed complex can be detected by a fluorescent microscope (Aoki et al., 2010; Huang et al., 2012). Pathogens such as *Toxoplasma gondii* can be detected by this method (Bernal-Guadarrama et al., 2014). This procedure is also commonly used for detecting pathogen-specific antibodies in autoimmune diseases such as systematic lupus erythematosus (SLE) (Ghosh et al., 2007). The example includes identifying the antinuclear antibodies (ANA) in the serum. ANA may be produced against different nuclear antigens in the serum of patients with a variety of rheumatic and nonrheumatic disorders. Another example is the fluorescent treponemal antibody absorption (FTA-ABS) test (Hunter, 1975). Treponema-specific antigens are coated on the slide, then the unknown serum is added. After washing and adding the labeled antibody, the result can be seen by a microscope. This test is usually performed if the initial screening tests (e.g., rapid plasma regain (RPR), venereal disease research laboratory (VDRL)) for syphilis are positive, so that this test can help confirm whether the results of screening tests are accurate. In general, the IIF has more sensitivity compared with DIF. In another technique based on IF staining, known as double IF, the presence of two different antigens on a cell can be identified.

Radio immunoassay (RIA)

RIA is an immunoassay using radiolabeled antibodies or antigens. Iodine isotopes such as ^{125}I , ^{131}I or tritium can be used for labeling. This method has high sensitivity but needs specialized equipment (e.g., gamma counter) for detecting radioactive signals. Furthermore, it requires special handling and disposal of radioactive waste. In this method, the unlabeled and labeled antigens compete for interaction with antibody molecules to form an antigen-antibody complex. The formed complex is then separated and precipitated with anti-immunoglobulin. The radioactivity of the precipitate indicates the bound antigens that is inversely correlated to the unlabeled antigen concentration (Goldsmith, 1975).

Chemiluminescence immunoassay (CLIA)

The basis of the CLIA method is similar to that of ELISA, except that CLIA substrates can generate light emission in the presence of an enzyme, providing a more sensitive process compared to ELISA. Substrates such as isoluminol or acridinium ester produce the luminescence signal in the presence of hydrogen peroxide and enzyme. The electro-chemiluminescence immunoassay (ECLIA),

another type of CLIA, uses electrical current for oxidizing substrate. CLIA and ECLIA methods have higher sensitivity compared to ELISA and ELFA and have a shorter analysis time (Liu et al., 2018).

Immunoblotting method

Immunoblotting or western blotting (WB) is a technique recognizing specific antibodies or antigens (e.g., pathogen antigens) in the sample. The presence of a certain protein and its molecular weight can be identified by WB. The method is based on a combination of gel electrophoresis and formation of the antigen-antibody complex (Ni et al., 2017; Magi and Liberatori, 2005). The procedure involves four important steps, as follows:

- 1) Protein separation by SDS-PAGE: the protein mixture is separated by SDS-PAGE based on the molecular weight of proteins.
- 2) Protein transfer from the gel to a nitrocellulose membrane by electrophoresis.
- 3) Incubation of the nitrocellulose membrane with serum sample: antigen-specific antibodies in the serum (primary antibodies) bind to the antigens on the nitrocellulose membrane.
- 4) Adding labeled secondary antibodies (specific to the primary antibodies) and detecting signals using either a chromogen or an X-ray film.

The antigen-antibody complexes can generate a visible band on the carrier membrane as a result of a dye reaction. By using known antigens, blot methods reveal a high specificity for detecting antibodies (e.g., HIV antibodies). However, WB has lower sensitivity compared to ELISA, ELFA and CLIA methods depending on the pathogen specificity. Therefore, it can be used as a confirmatory test (e.g., in borreliosis diagnosis) or as an additional test (e.g., toxoplasmosis, CMV, EBV diagnosis).

Nucleic acid-based identification methods

The principle of nucleic acid-based methods is the detection of specific DNA or RNA sequences of the microorganism. Nucleic acid-based approaches provide precise and sensitive identification and diagnosis of pathogens causing infectious diseases, as well as knowledge of the disease's epidemiology. These tests are rapid and have high specificity and sensitivity and can be used for the detection of all types of microbes. The recent development of the multiplex assay provides the detection of several different antigens in one analytical procedure. However, these tests are less sensitive or less specific than the single-target tests. In the following section, the most important nucleic acid-based methods are reviewed (Mothershed and Whitney, 2006; Mianzhi and Shah, 2017; Yu et al., 2012).

Polymerase chain reaction (PCR)-based amplification

PCR is an in vitro enzymatic reaction that enables large amounts of a particular DNA fragment to be generated. When compared to serologic tests, this method is more accurate and faster (Garibyan and Avashia, 2013; Ashford et al., 1995). Serologic tests are limited because of the window period required for production of sufficient levels of antibodies, so false-negative results can occur during this time. PCR can be applied even in the early phase of infection to detect the presence of a pathogen. For example, tuberculosis bacteria multiply slowly, making diagnosis via culture or serological methods time-consuming. In this condition, the PCR technique allows rapid amplification of the pathogen genes, leading to increased detection sensitivity and decreased detection time. Another example that highlights the importance of PCR in clinical diagnosis is Lyme disease, caused by a tick-borne spirochete. Using culture for detecting these bacteria is approximately impossible since they are too small to be seen by a microscope. Other examples are detecting Influenza virus, blood screening for human immunodeficiency virus (HIV), hepatitis B, hepatitis C and syphilis. Three important steps of PCR are as following (Fig. 3):

- 1) Denaturation: the use of high temperature at this step causes the double-stranded DNA to become single-stranded.
- 2) Annealing: as the temperature is reduced, the primers recognize and bind to the target DNA.
- 3) Extension: at this step, the complementary strand is made by a DNA polymerase enzyme at the appropriate temperature.

These three steps are generally repeated for 30–40 cycles. Importantly, the specificity of the designed primer to the target sequence determines the specificity of the PCR. After the reaction is over, the amplified DNA can be visualized using gel electrophoresis. Although computer software can estimate the amount of amplified DNA from the intensity of the band on the gel, PCR is not suitable for quantitative studies. For this purpose, quantitative PCR (qPCR) or real-time PCR (RT-PCR) has been developed. The PCR reaction can be monitored in RT-PCR through the emission of fluorescence during the reaction. These signals are recorded by the RT-PCR machine and are therefore traceable at the same time as the reaction is done. When compared to PCR, RT-PCR has a much higher degree of accuracy (Freeman et al., 1999).

Isothermal amplification

Isothermal nucleic acid amplification is a simple process that uses a constant temperature for the amplification of a nucleic acid target sequence instead of thermal cyclers required for PCR (Wong et al., 2018). Several isothermal amplification methods have been developed based on the mechanism of the reaction. Nucleic acid sequence-based amplification (NASBA) and Loop-mediated isothermal amplification (LAMP) are the most widely used isothermal methods. NASBA is an isothermal and continuous amplification based on RNA transcription, providing accurate results with high sensitivity (Compton, 1991; Morré et al., 1996).

Fig. 3 Schematic diagram of the polymerase chain reaction (PCR). These three steps are generally repeated for 30–40 cycles. Here, only 1 cycle is depicted.

It can be easily done in a water bath without the need for a thermocycler. The reaction takes place in the presence of a mixture of reverse transcriptase, RNA polymerase, ribonuclease-H, and two specially designed DNA oligonucleotide primers. A 5' extension of the forward primer includes the promoter sequence for bacteriophage T7 DNA-dependent RNA polymerase. A 5' extension of the reverse primer includes a sequence for binding a probe tagged with ruthenium-based electrochemiluminescent (ECL) that can be detected by a chemiluminescence detector (Lau et al., 2006). Under ideal conditions, the yield of amplification is nearly 10^{12} -fold, compared to 10^9 -fold amplification by PCR (Boom et al., 1990).

NASBA has been used extensively in the identification of a variety of viruses, including HIV-1, avian Influenza virus, Newcastle disease virus, Simian immunodeficiency virus, and Respiratory syndrome virus. This method can also be used in the detection of cytokines, bacteria (e.g., *Salmonella enterica*), fungi, and parasites (Romano et al., 1996, 2000; Collins et al., 2003; Lau et al., 2006).

LAMP is another isothermal amplification method conducted in the presence of a DNA polymerase (with a function for strand displacement) as well as two sets of primers (four different primers) (Zhao et al., 2015). Since amplification only occurs when all six sequences of a target DNA are accurately identified by the primers, the LAMP assay has a high specificity. However, the difficulties in developing usable primers restrict the practical application of LAMP. The amplification process continues in a cyclical manner. The end product is stem-loop DNA with multiple inverted copies of the target sequence. Positive LAMP reaction products can be identified using a variety of detection methods, such as incorporation of SYBR Green I stain or using polyethylenimine (PEI). This technique has been used in the detection of several viruses (e.g., Noroviruses, SARS-CoV, H5N1, avian Influenza subtypes, Influenza subtype 1, Influenza subtype 3, and Influenza B virus) and bacteria (e.g., *Salmonella*, *Escherichia coli* and *Mycobacterium tuberculosis*) (Hara-Kudo et al., 2005; Hill et al., 2008; Iturriza-Gómara et al., 2008; Poon et al., 2004; Imai et al., 2006; Geojith et al., 2011).

Microarray/chip-based technologies

The development of microarray/chip-based technology enables the analysis of samples with a large number of sequences in a single test (Raghavachari, 2013; Marzancola et al., 2016). Pathogen screening involves immobilizing the expressed sequences of various pathogens on a filter to determine which pathogens are present in the suspected samples. Therefore, a single procedure allows the detection of multiple pathogens. The basic principle of microarrays is the hybridization between two strands of DNA. In this procedure, a high number of specific DNA sequences known as probes or oligos are immobilized on a solid surface that are used to hybridize a nucleic acid of interest in the sample. The sample's nucleic acid is purified and labeled, typically with a fluorescent tag. The labeled samples are then added to the pinholes of the microarray. After hybridization has occurred, all nonspecific binding is washed off. Finally, the microarray is scanned by a machine through a laser to excite the dye and measures the emission levels with a detector.

Microarray-based methods have been used widely in screening clinical samples for viruses. This technique is also applied in single nucleotide polymorphisms (SNPs) analysis and in cancer diagnosis, such as detecting P53 mutations, and distal metastasis of lymph-node-negative primary breast cancer (Ahrendt et al., 1999; Wang et al., 2002, 2005; Chiu et al., 2006; Schick et al., 2011).

Non-nucleic acid-based identification methods

It is essential to identify an organism after it has been isolated by culture. The importance of identification is in the management of infectious diseases, such as choosing a better drug for treatment. Rather than genetic recognition, non-nucleic acid-based identification approaches depend on phenotypic characteristics of organisms, including functional or morphologic. There are several biochemical tests available, each of which is limited to species of a certain type (e.g., aerobic or anaerobic bacteria). However, two techniques, including chromatographic methods and mass spectrometry, are widely used for identifying pathogens.

High-performance liquid chromatography (HPLC) or gas chromatography can be used to isolate and identify microbial components or products. Typically, recognition is accomplished by comparing an organism's fatty acids to a database. In general, aerobic and anaerobic microbes, mycobacteria, and fungi can all be identified using chromatographic techniques. The accuracy of the test is determined by the circumstances under which the specimen was cultured and the accuracy of the database, which could be unreliable or inadequate (Larsson and Mårdh, 1977; Lima et al., 2018; Emonet et al., 2010).

Pathogens have distinct proteins, and the relative concentration and mass of each protein may often be used to classify a microorganism. Different proteins with different masses in a sample can be detected using mass spectrometry. A type of mass spectrometry known as matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) is currently being applied to recognize mycobacteria, yeasts, molds, and viruses (Patel, 2015).

Diagnostic laboratory tests: Focusing on immunological disorders

Autoimmune disorders

Autoimmunity is defined by a lack of immune homeostasis, which causes the organism to develop an abnormal reaction to its own tissue. Laboratory tests can be helpful in disease management and determining disease severity. The development of self-reactive T cells, autoantibodies, and inflammation are common features of autoimmune diseases. Diagnosing autoimmune disorders is complex and several laboratory tests are usually needed. These laboratory diagnosis tests include specific and non-specific tests such as complete blood count (CBC), evaluation of acute phase reactants and inflammatory markers, serological tests, cytokine analysis, and immunologic studies (Castro and Gourley, 2010). Laboratory diagnostic tests for evaluating autoimmune disorders are summarized in Table 1.

Inflammation-related markers

Inflammatory markers are serum proteins that are produced by the liver in response to inflammation. Pro-inflammatory cytokines such as IL-1, IL-6, and TNF-alpha produced by immune cells in the inflammatory condition play a significant role in stimulating the production of acute phase proteins such as C-reactive protein (CRP), fibrinogen, and haptoglobin. Inflammatory markers cannot be used to diagnose inflammation, although they can reveal abnormalities in a variety of conditions such as infections, autoimmune diseases, and malignancies (Gruys et al., 2005).

Erythrocyte sedimentation rate (ESR) is a test applied for the evaluation of the RBC's quantity. ESR is performed by analyzing the RBC sedimentation rate in a tube at a defined time. While ESR is a non-specific test and cannot be considered as a diagnostic test, it can be useful in controlling disease severity and therapeutic response, and can reflect the presence of inflammatory or infectious stress (Lahita and Weinstein, 2007).

CRP is an acute phase protein which can be induced under the influence of pro-inflammatory cytokines. This protein has an important activity in inducing phagocytosis through pathogen opsonization as well as complement activation. Since serum CRP concentrations shift faster than ESR, CRP could be a better indicator of current inflammation. On the other hand, in contrast to ESR, CRP is a stable serum protein that is not influenced by other serum components. CRP can be measured quantitatively and qualitatively (e.g., by CRP-latex described in the serological methods). The level of inflammation is proportional to the level of CRP. Levels of less than 0.2 mg/dL are regarded as normal, whereas levels greater than 1.0 mg/dL are indicative of inflammation and/or infection (Gruys et al., 2005; Lahita and Weinstein, 2007).

Ferritin is another serum protein that its increased levels may suggest acute or chronic sepsis, inflammation, or cancer. Ferritin is frequently increased in diseases such as systemic-onset juvenile idiopathic arthritis and lymphohistiocytosis. Other inflammatory markers include Ceruloplasmin, Fibrinogen, and Haptoglobin that can be increased during inflammation and autoimmunity disorders (Breda et al., 2010; Koulaouzidis et al., 2009).

Autoantibodies

The existence of autoantibodies in a patient does not imply a diagnosis of an autoimmune disorder. The signs and symptoms of the patient should also be carefully considered. Currently, ELISA (described in serological methods) is frequently used to detect autoantibodies in a suspected patient (Eggert et al., 2010).

"Rheumatoid factor" (RF) is an autoantibody produced against the FC region of IgG. RF is used to evaluate patients with rheumatoid arthritis (RA) with a sensitivity and specificity of about 70%. The RF can be any class of antibodies. However, most methods identify the IgM rheumatoid factor. It should be considered that approximately 15% of rheumatoid arthritis patients are negative for RF. On the other hand, RF may be positive in some healthy individuals. Although RF is considered as a non-specific test, patients with positive RF may experience progressive arthritis, extraarticular manifestations, and secondary Sjögren's syndrome. RF can be detected in other autoimmune diseases such as SLE, Sjögren's syndrome, and cryoglobulinemia. Identifying another autoantibody known as anti-citrullinated protein (anti-CCP) is also valuable in diagnosing RA patients (with about 95% specificity). Anti-CCP can be positive in psoriatic arthritis, Sjögren's syndrome, juvenile idiopathic arthritis (JIA), and inflammatory myopathies (Lahita and Weinstein, 2007; Klippel et al., 2008).

"Anti-nuclear antibody" (ANA) is another autoantibody which is mostly used in the diagnosis of SLE. However, ANA can be found in other diseases, including RA, scleroderma, Sjögren's syndrome, mixed connective tissue disease, and polymyositis/dermatomyositis. The immunofluorescence method is frequently used for detecting ANA in patients' serum. ELISA technique is

Table 1 Laboratory diagnostic tests for evaluating autoimmune diseases.

<i>Autoimmune disorder</i>	<i>Laboratory diagnostic tests</i>
Rheumatoid arthritis (RA)	• CRP and ESR: non-specific, initial screening, indication of inflammation • RF: not specific, present in about 80% of patients with RA, associated with poor prognosis • Anti-CCP: more sensitive and specific compared to RF, present in about 80% of patients with RA • ANA: about 60% specificity and 45% sensitivity in patients with RA • HLA-Typing: HLA-DRB1 variations
Systemic lupus erythematosus (SLE)	• CBC: anemia, low WBC or platelet count maybe seen • ANA: positive in about 100% of the patients with SLE, higher sensitivity (about >95%) • Anti-dsDNA, higher specificity (about 95%), usually associate with active disease • Anti-Extractable Nuclear Antigens: Anti-sm (high specificity), anti-RNP, Anti-SSA (anti-Ro), Anti-SSB (anti-La) • Urinalysis in renal involvement: hematuria, proteinuria, present WBC • Complement assay: decreased level of C3 and C4, decreased CH50 • Kidney biopsy
Goodpasture's syndrome	• Urinalysis: indicates proteinuria, dysmorphic RBCs, WBCs, and RBC cellular and granular casts • Anti-GBM • Kidney biopsy
Sarcoidosis	• The levels of serum ACE: elevated levels may be seen, but this test is non-specific • The levels of Vitamin D: increased levels of 1, 25(OH)2D3 vitamin D are commonly seen • The levels of SAA: increased levels of SAA are commonly seen
Churg-Strauss syndrome	• CBC: indicates a peripheral eosinophilia • ESR and CRP: elevated levels are seen • ANA and a p-ANCA against MPO • A biopsy of the involved organ: for evaluation of vasculitis and granuloma formation
Wegener's granulomatosis (WG)	• ESR and CRP: elevated levels are seen • C-ANCA-PR3 • HLA-Typing: WG can be associated with HLA-DR4, DR13 • Urinalysis: proteinuria, hematuria, cellular casts • The levels of serum albumin: hypoalbuminemia
Myositis	• CBC: May show leukocytosis or thrombocytosis • Muscle biopsy • MSA: Anti-tRNA synthetase antibodies (anti-JO-1 antibodies), Anti-SRP, Anti-PM/ScI, Anti-Mi-2 • HLA-Typing: myositis can be associated with HLA-DRB1 *0301 and HLA-DQA1 *0501 • The levels of CK, AST, ALT and LDH
Autoimmune hemolytic anemia (AIHA)	• Peripheral blood smear: polychromasia, spherocytosis, fragmented and nucleated erythrocytes Reticulocytosis, erythrophagocytosis by monocytes in severe cases • The levels of haptoglobin: decreased levels are seen • The levels of LDH: increased levels are seen • DAT: evaluation of immunoglobulin and/or complement proteins bound to the patient's erythrocytes
Antiphospholipid syndrome	• CBC: thrombocytopenia • aPL
Idiopathic Thrombocytopenia	• Thrombocytopenia • human platelet antigen—1a antibodies

CRP, C-reactive protein; ESR, Erythrocyte sedimentation rate; RF, Rheumatoid factor; CCP, Cyclic citrullinated peptide; ANA, Anti-nuclear antibody; HLA, Human leukocyte antigen; CBC, Cell blood count; WBC, White blood cell; SLE, Systemic lupus erythematosus; dsDNA, Double stranded DNA; Anti-sm, Anti-smith; anti-RN, Anti-ribonucleoprotein; Anti-SSA, Anti-Sjögren's-syndrome type A; Anti-SSB, Anti-Sjögren's syndrome type B; CH50, Hemolytic complement; Anti-GBM, Anti-glomerular basement membrane antibodies; ACE, Angiotensin converting enzyme; SAA, Serum amyloid A; ANCA, Antineutrophil cytoplasmic antibodies; p-ANCA, Perinuclear-ANCA; c-ANCA, Cytoplasmic-ANCA; MPO, Myeloperoxidase; PR3, Proteinase 3; WG, Wegener's granulomatosis; MSA, Myositis-specific antibodies; Anti-PM/ScI, Antibody to nucleolar granular component; Anti-SRP, Antibody to signal recognition protein; CK, Creatinine kinase; AST, Aspartate aminotransferase; ALT, Alanine transaminase; LDH, Lactate dehydrogenase; DAT, Direct anti-globulin test; aPL, Antiphospholipid antibody.

also used with high sensitivity but low specificity. ANA is also found in nonrheumatic disorders such as autoimmune hepatitis, Hashimoto's thyroiditis, primary pulmonary hypertension, Graves' disease, and primary autoimmune cholangitis (Sur et al., 2018; Grygiel-Górniak et al., 2018). Furthermore, ANAs are also associated with several infections, such as *Mycobacterium tuberculosis*, *Treponema pallidum*, *Orientia tsutsugamushi*, *Escherichia coli*, *Bartonella henselae*, and human immunodeficiency virus (Im et al., 2020).

Other antibodies that are important and highly specific in diagnosing SLE are "anti-double stranded DNA" (anti-dsDNA). Although anti-dsDNA was previously detected by radioimmunoassay, IFA and ELISA are more commonly used currently. Crithidia luciliae, a flagellated protozoa with a dsDNA-containing small organelle called a kinetoplast, is used as a target antigen by the IFA. Semiquantitative detection of antibodies against dsDNA is accomplished by detecting IgG attached to the kinetoplast. In ELISA, the dsDNA is coated on a microtiter plate and the bound IgG is detected after adding the suspected serum (Lahita and Weinstein, 2007; Mummert et al., 2018; Conrad et al., 2009).

“Antineutrophil cytoplasmic antibodies” (ANCA) are produced against the cytoplasmic granules of neutrophils. The immunofluorescent patterns can be useful in diagnosing various ANCA associated vasculitis syndromes. Cytoplasmic pattern (cANCA) is frequently found in Wegener’s Granulomatosis (WG), microscopic polyangiitis (MPA) and Churg-Strauss syndrome. Perinuclear pattern (pANCA) can be seen in MPA as well as in RA, inflammatory bowel disease (IBD), JIA, and SLE. The vasculitis type and disease severity can also be identified by detection of proteinase 3 (PR3) and myeloperoxidase (MPO). For example, MPO-cANCA is particularly associated with WG. MPO-pANCA is positive in MPA and less often for Churg-Strauss. It should be considered that ANCA can also be positive in some conditions, such as during thyroid medication (e.g., PTU) and other immune disorders. Tissue biopsy can be helpful for confirming patients suspected of vasculitis (Schönermarck et al., 2001; Csernok and Gross, 1995).

“Anti-extractable nuclear antigen” (anti-ENA) are a group of antibodies against extractable antigens, including SSA (Ro) and SSB (La) nuclear antigens, Smith (Sm) antigen, and ribonuclear protein (RNP) or U1RNP. Anti-SSA and anti-SSB antibodies are usually seen together in Sjögren’s syndrome patients and some patients with SLE.

Anti-Sm is particularly specific for SLE; However, it is only present in 25% of SLE patients. Antibodies to U1 ribonucleoproteins have been detected in several autoimmune diseases such as SLE, systemic sclerosis, and in patients with mixed connective tissue disease (Agarwal et al., 2009).

Autoantibodies known as anti-JO-1, anti-Mi-2, anti-SRP, and anti-PM/Scl have been detected in the autoimmune inflammatory myopathies (IIM) with high specificity. Anti-JO-1 antibodies are produced against histidyl-tRNA synthetase and are particularly seen in anti-synthetase syndrome, an inflammatory myopathy. Anti-Mi2 antibodies can target a nuclear complex involved in transcription. These autoantibodies are specific for diagnosing dermatomyositis. Anti-signal recognition particles (SRP) are antibodies against a cytoplasmic RNA protein involving 7S RNA and 6 other proteins. Anti-SRP has been detected in the serum of polymyositis patients. These antibodies are considered as serological markers for identifying necrotizing myopathy. Anti-PM/Scl is a type of antinuclear antibody associated with idiopathic inflammatory myositis-systemic sclerosis overlap syndromes (also called scleromyositis or sclerodermatomyositis). These types of autoantibodies have also been found in patients with polymyositis, dermatomyositis and systemic sclerosis without features of overlap syndromes (Satoh et al., 2017).

Autoantibodies named as antiphospholipid autoantibodies (aPL) or lupus anticoagulant (LAC) or anti-cardiolipin (aCL) are produced against phospholipids as well as phospholipid-binding proteins. These antibodies have been found in patients with anti-phospholipid antibody syndrome (APS) as well as SLE patients. aPL antibodies may also be detected in healthy individuals (McIntyre et al., 2003; Coín et al., 2015).

Complement activity

The complement system is an enzymatic cascade consisting of several proteins in the serum. Complement activation can be considered as an important pathway in defending against pathogens. Meanwhile, the levels of complement components in the serum can be used to identify disease activity. The methods for measuring complement components include nephelometry and ELISA for detecting components such as C3, C4 and factor B. The hemolytic activity of complement can be assayed using CH50 and AH50 which analyze the functional activity of the classic and alternative pathways, respectively. In diseases in which the immune complex is formed in tissues, such as glomerulonephritis in patients with SLE, the serum levels of complement’s proteins decrease. In contrast, elevated levels of C3 and C4 in the acute phase of the disease can suggest an inflammatory disorder. A decreased level of complement components has been found in nonrheumatic disorders such as post-streptococcal glomerulonephritis or bacterial endocarditis (Conigliaro et al., 2019; Boackle, 2003).

Cytokines

Cytokines are glycoproteins produced by several immune and non-immune cells, playing an important role in immune function and the development of inflammation. Flow cytometry and ELISA are laboratory techniques used to evaluate cytokine levels. For this reason, sandwich ELISA is frequently used by commercial kits. Although evaluation of the gene expression levels of cytokines can be applied by molecular tests, particularly Real-Time PCR, this process is usually performed in research laboratories.

Assessing pro-inflammatory cytokines, especially IL-1, IL-6, and TNF-alpha can be helpful in detecting an inflammatory disorder. Since the level of pro-inflammatory cytokines is increased in autoimmune disorders, targeting these molecules is used as an effective therapeutic approach. For example, targeting TNF-alpha through monoclonal antibodies (mAbs) can significantly reduce disease severity in patients with RA. Using mAbs, including anti-TNF, anti-IL-1 and anti-IL-6 therapies, is currently being used in several immune disorders (O’Shea et al., 2002; Moudgil and Choubey, 2011).

Human leukocyte antigen (HLA) typing

The association between HLA or Major Histocompatibility Complex (MHC) and immune disease susceptibility has been described in many studies. HLA-A, -B and -C are the classic types of MHC class I molecules, and HLA-DR, HLA-DQ, and HLA-DP are MHC class II molecules. It has been found that many rheumatic disorders are associated with HLA class I and II. For example, HLA-B27 is highly associated (about 90–95%) with susceptibility to ankylosing spondylitis. HLA-DR1 and HLA-DR4 are associated with an increased risk of polyarticular juvenile idiopathic arthritis (JIA). In Caucasian populations, HLA-DR3 and HLA-DR2 are associated with lupus, while HLA-DRB1 is associated with an increased risk of rheumatoid arthritis (Troshina et al., 2020).

HLA-typing is also considered an important test before organ transplantation (especially bone marrow transplantation) to identify which people can provide the safest tissue transplants. In this regard, the best potential donors have HLAs that closely match the recipient’s HLA profiles. Several methods can be used to detect HLA types, including serological- and molecular-based methods (Wiebe and Nickerson, 2020).

Serological typing (traditional method) is frequently used in many laboratories for identifying HLA-A and HLA-B with low resolution. This method is performed using a complement-dependent cytotoxicity (CDC) test or micro lymphocytotoxicity assay. In this procedure, a panel of sera containing HLA-specific alloantibodies is added to a well of a microtiter Terasaki plate consisting of the patient's lymphocytes. Rabbit serum containing complement is added after a short incubation time. The lymphocytes that have been recognized by a specific alloantibody undergo lysis, allowing the fluorochrome ethidium bromide to enter. The lysed cells can simply be identified by microscopy (Saito et al., 2014).

Molecular testing provides HLA-typing with more resolution using the PCR technique. These tests including sequence-specific primer (SSP) and sequence-specific oligonucleotide (SSO) are very useful and both of them can apply either for generic (low resolution) and allelic (high resolution) typing. SSP provides identification of HLA-A, -B, -C, -DRB1, -DRB3, -DRB4, -DRB5, and -DQB1 alleles. SSP typing includes using primers that are complementary to specific HLA allele sequences (e.g., HLA*02:03) or a set of identical alleles (e.g., all A*02 alleles). The presence of the product is then detected by agarose gel electrophoresis. This method is performed rapidly and is ideally appropriate for small numbers of samples (Madden and Chabot-Richards, 2019; Kulcsarova et al., 2000).

Sequence-specific oligonucleotide (SSO) was first described for HLA class II and then for HLA class I typing. In this method, locus-specific amplification of the genomic DNA segment is initially performed by PCR. After that, the amplified DNA is blotted onto a solid support, normally a nylon membrane, and hybridized with a series of sequence-specific oligonucleotide probes (SSOP) (direct hybridization). The probes are bound to the fluorochromes, allowing their detection by chemiluminescence. In indirect hybridization, SSO probes are attached to a solid phase and then hybridized with a labeled PCR product. The SSO method is very suitable for the typing of large sample numbers. However, a method known as reverse-SSO has been developed for testing low sample numbers. In this method, a pre-made SSOs bound membrane is used. Sample DNA is specifically amplified using specific primers for certain HLA locus. Amplified DNA is labeled (e.g., with biotin) and then added to the SSOs bound membrane. Finally, the hybridization result is detected using a colorimetric or chemiluminescent detection system. Recently, a reverse-SSO system is developed based on Luminex technology. All methods, including SSP, SSO and reverse-SSO, are all appropriate for application in research and also in routine tissue typing laboratories (Madden and Chabot-Richards, 2019; Kulcsarova et al., 2000).

Another technology known as Sequence-based typing (SBT) is a comprehensive molecular-based method with high resolution. This technique is based on the sequencing of amplified DNA. Both alleles for each HLA locus are amplified and then sequenced. Although PCR-SSO is able to detect single-base variations in DNA sequences within two alleles, it is less likely to detect new undefined alleles unless the variation occurs at the particular site detected by the probe or the restriction enzyme. Furthermore, this method is more expensive compared to other methods (Voorter et al., 2014).

Immunodeficiency disorders

Immunodeficiency disorders are referred to a group of diseases in which the immune system is compromised because of defects in innate immune system (e.g., complement pathway, phagocytosis) or adaptive immune system (e.g., cellular and humoral immunity). Primary immunodeficiencies are determined genetically and they are usually revealed during infancy or childhood. Secondary immunodeficiencies can result from other disorders or conditions such as diabetes, radiation therapy, chemotherapy, bone marrow ablation before transplantation, etc. There are a variety of diagnostic laboratory tests for diagnosing defects in the immune system (Rezaei et al., 2009; Raje and Dinakar, 2015). Laboratory diagnostic tests for evaluating primary immunodeficiencies are summarized in Table 2. We will review these tests in the following sections.

Initial screening

In general, recurrent infections are a common symptom of immunodeficiency. The patient can experience up to 10 respiratory infections/year. Therefore, a careful history of the patient to assess infectious diseases and other complications is crucial to diagnosis of an immunodeficiency disorder. In this regard, manifestations such as failure to thrive (FTT), upper and lower respiratory tract infections (e.g., pneumonia, sinusitis, bronchitis), and chronic diarrhea can be considered as frequent manifestations importantly in a patient with primary immunodeficiency. Therefore, it is essential to evaluate clinical manifestations along with laboratory diagnostic assays. Initial laboratory tests for screening such patients should include complete blood counts (CBC) and differentials (platelet volume, absolute lymphocyte count, neutrophil and eosinophil counts), immunoglobulin levels (IgG, IgM, IgA), lymphocyte subpopulations, vaccine titers, and complement assessment (e.g., CH50, AH50).

CBC results can detect abnormalities in one or more cell types, which can be a clue to detect a specific disorder. These abnormalities include anemia, neutropenia, thrombocytopenia, and lymphopenia. For example, since T cells account for about 70% of circulating lymphocytes, lymphopenia could suggest a T-cell associated deficiency. A patient with persistent leukocytosis, especially between infections, may suspect a leukocyte adhesion deficiency. Wiskott-Aldrich syndrome can be initially screened by thrombocytopenia. On the other hand, decreased levels of immunoglobulins can suggest antibody deficiency. However, these assessments are often inadequate to make a diagnosis. Therefore, several complementary tests should be performed when the screening tests and clinical manifestations are in favor of an immunodeficiency disorder. These tests are usually performed to assess immune cell function (Locke et al., 2014; Eghbali et al., 2015).

Humoral immunity deficiency

When a humoral immunity-related immunodeficiency is suspected, quantitative immunoglobulin analysis (IgG, IgA, IgM, and IgE) is the most important early screening. Furthermore, the evaluation of specific antibody titers is important. In this regard, serum titers to common vaccinations such as diphtheria, tetanus, and pneumococcus can be used. ELISA is frequently used to detect antibody titers in the serum.

Table 2 Laboratory diagnostic tests for evaluating primary immunodeficiencies.

<i>Laboratory diagnostic tests</i>	
Initial screening	• CBC and differential (platelet volume, absolute lymphocyte count, neutrophil and eosinophil counts) • Immunoglobulin levels (IgG, IgM, IgA) • Lymphocyte subpopulations • Vaccine titers (e.g., diphtheria, tetanus, and pneumococcus) • Complement assessment (e.g., CH50, AH50)
Humoral immunity deficiency	• CBC and differential • Quantitative immunoglobulin analyzes (IgG, IgA, IgM, and IgE) • Specific antibody titers • B cell immunophenotyping (e.g., IgM, IgD, IgG, CD19, CD20, CD27, and CD38) • Genetic mutational analysis (BTK, TACI, BAFFR, ATM, CD79a, CD79b, BLNK, LRRC8, AID, UNG) • KREC
Cellular immunity deficiency	• CBC and differential • T cell immunophenotyping (e.g., CD3, CD4, CD8) • T cell cytotoxicity assay • CD45RA/RO status • DTH tests • Stimulation with mitogens • TREC • Genetic mutational analysis
Combined immunodeficiency	• CBC and differential • Immunophenotyping: T, B, NK cells • Genetic mutational analysis RAG1, RAG2, IL-2 gamma chain, JAK3, CD3, Artemis, Cernunnos, Ligase 4, IL-7 receptor alpha, ADA, PNP, AK2, ZAP70, CD45, DNA-PK, NHEJ1, CD40, CD40L
Innate immunity deficiency	• CBC and differential • Absolute neutrophil count, and morphological analysis of neutrophils • CD11, CD18, CD15c levels: evaluating for LAD • Integrin function • DHR assay • NBT assay • G6PD analysis • NK cytotoxicity and NK markers • Complement assay • Genetic assessment: ELA2, GFI-1, HAX1, GCSFR, MPO

CRP, C-reactive protein; *Ig*, Immunoglobulin; *CH50*, Hemolytic complement (classic pathway); *AH50*, Hemolytic complement (alternative pathway); *BTK*, Bruton's tyrosine kinase; *TACI*, Transmembrane activator and CAML interactor; *BAFFR*, B-cell activating factor receptor; *ATM*, Ataxia telangiectasia mutated; *BLNK*, B-cell linker protein; *LRRC8*, leucine-rich repeat-containing 8; *AID*, Adenosine deaminase; *UNG*, Uracil N-Glycosylase; *KREC*, Kappa-deleting recombination excision circle; *DTH*, Delayed-type hypersensitivity; *TREC*, T-cell replication excision circle; *RAG*, Recombination-activating gene; *JAK3*, Janus kinases; *ADA*, Adenosine deaminase; *PNP*, purine nucleoside phosphorylase; *AK2*, Adenylate Kinase 2; *ZAP70*, Zeta-chain-associated protein kinase 70; *NHEJ1*, non-homologous end joining-1; *CD40L*, CD40-Ligand; *LAD*, Leukocyte adhesion deficiency; *DHR*, Dihydrorhodamine; *NBT*, Nitro blue tetrazolium; *G6PD*, Glucose-6-phosphate dehydrogenase; *NK*, Natural killer cell; *ELA2*, Elastase 2; *GFI-1*, Growth Factor Independent 1; *HAX1*, HCLS1 Associated Protein X-1; *GCSFR*, Granulocyte colony-stimulating factor receptor; *MPO*, Myeloperoxidase.

There are several advanced methods which should be performed on a patient suspected of humoral immune deficiency. Analysis of the expression of B cell markers can be used to assess the B cell phenotype as well as the maturation state of B cells. Important markers used for B cell immunophenotyping include IgM, IgD, IgG, CD19, CD20, CD27, and CD38. IgM and IgD are expressed on mature B cells, but CD27 and CD38 are absent on these cells. CD27 can represent active/memory B cells and CD38 is a marker for antibody-secreting cells and plasma cells. For example, in a patient with common variable immunodeficiency (CVID) decreased levels of memory B cells (CD27⁺, IgM⁻, IgD⁻) are found. Or in patients with X-Linked Agammaglobulinemia (XLA or Bruton), a low or absent circulating B cell population is seen (Aghamohammadi et al., 2005; Moin et al., 2004).

Genetic mutational analysis is another important assessment to detect certain immunodeficiency. This approach can be performed by genome sequencing accompanied with flow cytometry for analyzing the levels of associated protein. For example, a genetic defect in the Bruton's Tyrosine Kinase (BTK) gene is linked to XLA, while a defect in the transmembrane activator and calcium-modulating cyclophilin ligand interactor (TACI) and BAFFR genes is linked to CVID. Or alterations of the ataxia-telangiectasia mutated (ATM) gene are associated with Ataxia-Telangiectasia. By using flow cytometry, intracellular expression of BTK, TACI, BAFFR, and ATM can be identified (Moin et al., 2004; Mohammadi et al., 2009; Zaki-Dizaji et al., 2017; Losi et al., 2005).

Kappa-deleting recombination excision circle (KREC) analysis is another approach to identifying a patient with a humoral immunodeficiency disorder. KRECs are episomal DNA fragments produced during the development of B lymphocytes, importantly when the kappa light-chain genes are being rearranged. PCR can be used to detect KRECs in newborn blood spots, providing a screen for B cell-related deficiencies like XLA and ataxia-telangiectasia (Serana et al., 2013).

Cellular immunity deficiency

In a patient who is suspected of having cellular immunodeficiency, a CBC with differential can be performed to distinguish infants with low/absent absolute lymphocyte counts. Subsequently, flow cytometry and in vitro functional tests can be applied to evaluate the quantity and function of T lymphocytes. Flow cytometry can distinguish between CD3, CD4, CD8, natural killer (NK), and B cell numbers. Immunophenotyping is also important for the diagnosis of severe combined immunodeficiency (SCID). CD3, CD4, and CD8 are T lymphocyte markers that are frequently decreased in defects associated with cellular immunity such as DiGeorge Syndrome. CD45RA is a marker identifying naïve T cells in infants, while CD45RO is considered as a memory T cell marker for identifying maternal T cells. In Omenn syndrome, a variant of SCID, increased frequencies of CD45RO+ T cells are found (Locke et al., 2014; Shahbazi et al., 2019).

Another method for assessing T cell function is the cutaneous delayed-type hypersensitivity (DTH) tests. In these tests, the cellular mediated memory response is detected by intradermal injection of different antigens, including purified protein derivative (PPD), *Candida albicans*, and mumps. The result is assessed 48–72 h later by measuring cutaneous induration. It should be noted that DTH is not recommended for children less than 12 months of age.

The Lymphocyte mitogen assay is another important test for assessing T cell function. In this test, T-cell mitogens are used to stimulate the lymphocytes. The quantification is performed by adding radiolabeled thymidine that is able to be incorporated into the DNA of proliferating cells. Anti-CD3 antibodies, Phytohemagglutinin (PHA), concanavalin (ConA), pokeweed (PWM), and *Escherichia coli* lipopolysaccharide (LPS) are commonly used as mitogens. In this regard, anti-CD3 antibodies, PHA, and ConA are T cell mitogens; LPS is a B cell mitogen; PWM can induce both T cells and B cell responses (Raszka et al., 1996; Ahmed and Blose, 1983).

T-cell replication excision circle (TREC) was recently developed for earlier screening of newborns with severe T cell lymphopenia. Assessing patients using TREC has helped to improve early diagnosis and reduce morbidity and mortality. TREC is referred to the circular, non-replicating pieces of DNA produced during the rearrangement of T cell receptor and they can be considered as a marker for naïve T cells (Somech, 2011).

Genetic investigation of certain genes is considered as another approach to detect cellular immunity defects as well as combined immunodeficiency in which both cellular and humoral immune systems are affected. The genetic assessment can be performed along with the analysis of protein level in the patient's sample.

Quantitative real-time PCR provides the detection of mutations with high sensitivity and specificity. For example, a mutation in the WAS protein (WASp) is associated with WAS. The detection of WASp using Flow cytometry can rapidly screen for this disorder. However, there is a newer method to detect gene alterations known as fluorescent in situ hybridization (FISH). Deletions at 22q11 that occur in DiGeorge Syndrome can be detected by this method (Stewart et al., 2007; Stachon et al., 2007).

Various phenotypes of SCID have been identified by their causative genetic deficiencies, including T-/B+/NK-, T-/B+/NK+, T-/B-/NK+, T-/B-/NK-. Genetic analysis and flow cytometry can detect defected genes. Common gamma chain (CD132) or Janus Kinase 3 (Jak3) deficiency can lead to X-linked SCID (T-/B+/NK- phenotype), the most frequent type of SCID. Deficiency in IL-7 receptor alpha, CD3, CD45, ZAP70, and Coronin-1A are related to T-/B+/NK+ Phenotype of SCID. The T-/B-/NK+ phenotype is associated with gene defects in recombination activating genes-1 (RAG-1) or RAG-2, Artemis, Ligase4 (LIG4), DNA-dependent protein kinase (DNA-PK or PRKDC), and Cernunnos (NHEJ1). In addition, adenosine deaminase (ADA), purine nucleoside phosphorylase (PNP), and adenylate kinase 2 (AK2) deficiencies are associated with the T-/B-/NK- phenotype (Fallah et al., 2018; Locke et al., 2014).

Innate immunity deficiency

There are several disorders related to deficiencies in the innate immune system. Neutrophil-associated disorders are usually characterized by recurrent skin and respiratory tract infections. Other manifestations include delayed umbilical cord separation, poor wound healing, recurrent oral stomatitis, and omphalitis. CBC, absolute neutrophil count, and morphological analysis of neutrophils are considered as initial screening tests (Duchamp et al., 2016; Wong et al., 2013).

Leukocyte Adhesion Deficiency (LAD) is characterized by recurrent bacterial infections, delayed umbilical cord separation, or omphalitis. Three different types of LAD are defined by different gene mutations in molecules involved in leukocyte adhesion. The decreased level of expression of CD11 or CD18 using flow cytometry is considered as a diagnostic test for LAD type 1 (LAD-1). Abnormal expression of CD15c (sialyl lewis X) on neutrophils by flow cytometry is suggestive of LAD-2. In another type of LAD, LAD-3, the function of adhesion molecules is impaired. Therefore, analyzing the function of integrins in leukocytes or platelets is helpful in diagnosing LAD-3 (Etzioni, 2007; Parvaneh et al., 2010).

Chronic granulomatous disease (CGD) is another deficiency related to a defect in the innate immune system components. CGD is characterized by recurrent bacterial and fungal infections due to reduced or absent oxidative burst. CGD can be diagnosed through flow cytometric assessment of the neutrophil oxidative burst by the dihydrorhodamine (DHR) assay. This test is performed by incubation of neutrophils with DHR dye. After that, neutrophils are stimulated by adding phorbol myristate acetate (PMA). PMA induces oxidative burst in neutrophils, resulting in DHR oxidization and fluorescence production. This test is usually abnormal in a patient with CGD. Nitro blue tetrazolium (NBT) is another colorimetric assay previously defined for CGD evaluation. In general, DHR is more sensitive than NBT (Movahedi et al., 2004; Arnold and Heimall, 2017).

Two other disorders also have similar manifestations to CGD, including myeloperoxidase deficiency and glucose-6-phosphate dehydrogenase deficiency (G6PD). Although the DHR assay can be a testing option for diagnosing an MPO-deficient patient,

histochemical staining of MPO is considered as the definitive diagnosis of this disorder. G6PD is also detected by DHR, but the assessment of G6PD activity is also required in patients with recurrent infections or chronic anemia (Frank, 2005; Froissart et al., 2011).

Defects in NK cell numbers and their function result in recurrent infections and the clinical phenotype of hemophagocytic lymphohistiocytosis (HLH), respectively. For screening of suspected patients, immunophenotyping should be performed to verify the existence or absence of NK cells. CD16, CD56, and CD57 markers are usually used for immunophenotyping of NK cells using flow cytometry. On the other hand, evaluation of NK cell function can be performed by a cytotoxicity assay. This test can be done by incubating the peripheral blood mononuclear cells (PBMCs) isolated from suspected patients with labeled target cells. Subsequently, analyzing the markers associated with cell death or apoptosis, such as annexin V by flow cytometry, should be performed. In addition, assessment of CD107a by flow cytometry can be done to investigate the existence of intracellular cytotoxic proteins such as perforin and granzyme. CD107a is a marker involved in cell degranulation. Importantly, the defective expression of CD107a is considered as a diagnostic marker in patients with Griscelli syndrome, Chediak-Higashi, and familial HLH. Cytotoxicity assay can also be done for evaluation of the cytotoxic function of cytotoxic T lymphocytes (CTLs), the cells involved in cellular immunity (Orange, 2013).

Another defect in the innate immune system, complement system deficiency, can be evaluated by analyzing the level or function of the complement system using CH50 and AH50 methods. The hemolytic activity of the classic pathway is measured by CH50 assay, while the function of the alternative pathway is measured by AH50. Therefore, the deficiency in the components of the classic pathway, including C1, C2, and C4 deficiency, leads to a decreased level of CH50 but a normal AH50. On the other hand, a low level of AH50 (with normal CH50) can suggest a defect in the alternative pathway's components such as factor B, factor D, or properdin (Kirschfink and Mollnes, 2003; Frank, 2000; Pettigrew et al., 2009).

Identification of bacteria—general considerations

Rationale and justification

The goal for clinical microbiology laboratories is to provide a rapid and accurate identification of all agents including bacteria involved in infectious disease processes. While laboratories try to achieve 100% accuracy, many factors impact how successful a laboratory is in approaching this theoretical goal.

There are a number of reasons why an accurate species identification of medically important bacteria is essential and some of these are listed in Table 1. By far the single most important reason is to provide a physician with critical information regarding the cause of an infection (diagnosis and prognosis) and treatment modalities (intervention). Other important reasons for definitive species identifications include epidemiological considerations involving tracking and monitoring of infectious outbreaks in communities or healthcare settings or identifying vehicles associated with illnesses resulting from the consumption of contaminated consumable products. Outbreaks, often linked to specific pathogens and subtypes, can take on national or global importance when they evolve from a local stage. Definitive bacterial identifications can also lead to the discovery of new infectious agents or novel disease syndromes associated with classic pathogens with new virulence-associated characteristics. Finally, and not to be overlooked, is the need for a definitive identification when publishing peer-reviewed articles in scientific journals. Failure to correctly identify bacteria to species in such situations can lead to a medical literature replete with incomplete or inaccurate descriptions of phenotypic or genetic properties, species—disease associations, syndromes, and appropriate treatment regimens (Janda, 2002). Illustrative examples of the importance of definitive species identifications in certain situations are shown in Table 2.

The evolution in testing methodologies

Beginning in the late 1960s and continuing to this day technologic developments have ushered in a new era in regards to test menu options in the laboratory identification of bacteria. Fig. 1 shows the evolutionary process with some of the notable accomplishments in the development of these testing technologies between 1960 and 2020. Early seminal achievements included the miniaturization and automation of standardized test panels and combination panels with both identification and antimicrobial susceptibility results (Janda and Abbott, 2014). Such tests as the API 20E (bioMérieux Inc., Durham NC), still in use today, were developed during the early 1970s and consisted of a panel of 21 tests including an oxidase reaction. By the mid-1980s to the early

Table 1 Reasons for the Accurate Species Identification of Bacteria.

Relative priority	Category	Comment	CLIA Regulated
1	Diagnosis or prognosis	Including recurrent infections	Yes
1	Therapeutic intervention	Species-specific chemotherapy	Yes
2	Epidemiology	Disease investigations including outbreaks, epidemics and pandemics	No
2	Infection Control	Environmental surveillance for vehicles of infection	No
3	Detection of new infectious agents	New species descriptions isolated from clinical samples	Yes
3	New syndromes	In recognized or novel taxa	No
4	Research	Species-associated pathogenicity	No
5	Publications	Defining diseases, syndromes, outbreaks, or treatments associated with specific species or groups	No

CLIA, Clinical Laboratory Improvement Amendments.

Table 2 Examples of the importance of definitive bacterial identifications.

Category	Agent	Distinguish from	Disease Associations	Comments	References
New Infectious Agents	<i>Acinetobacter seifertii</i> <i>Acinetobacter variabilis</i>	Other <i>Acinetobacter</i> species	Sepsis, Wounds, Respiratory	Large groups of strains	Nemec et al. (2015)
Treatment Epidemiology	<i>Aeromonas</i>	<i>Vibrio</i> spp.	Sepsis, Wound infections	Inducible β -lactamases; carbapenemases; environmental source	Sinclair et al. (2016)
Prognosis	<i>Burkholderia cenocepacia</i>	<i>Burkholderia multivorans</i>	Cystic Fibrosis	Poorer prognosis associated with <i>B. cenocepacia</i>	Drevinek and Mahenthiralingam (2010)
Species-Associated Pathogenicity; Treatment	<i>Clostridioides difficile</i>	Same as <i>Clostridium difficile</i>	Gastrointestinal disease	Hypervirulent strain (NAP1/B1/027); poor clinical response to metronidazole	Lo Vecchio and Zacur (2012)
Diagnosis Prognosis Epidemiology	<i>Clostridium septicum</i> <i>Elizabethkingia anophelis</i>	Other clostridial species <i>Elizabethkingia meningosepticum</i>	Aortitis Gas Gangrene Sepsis	Linked to colorectal carcinoma Multiple Midwest outbreaks; new pathogenic species	Jessamy et al. (2016) Janda and Lopez (2017)
New Syndrome Species-Associated Pathogenicity	<i>Klebsiella pneumoniae</i>	No change	Pyogenic liver abscess Pneumonia Endophthalmitis	Hypervirulent (muroid K1/K2 strains)	Jun (2018)
Diagnosis	<i>Pseudomonas aeruginosa</i>	Fluorescent pseudomonads	Sepsis	Septicemia vs. pseudo-bacteremia or catheter-associated	Scales et al. (2014)
Treatment	<i>Staphylococcus pseudintermedius</i>	<i>Staphylococcus aureus</i> and <i>S. intermedius</i> group	Sepsis Chronic rhinosinusitis SSTI	Methicillin resistance	Somayaji et al. (2016) and Canver et al. (2019)
Diagnosis Prognosis	<i>Streptococcus bovis</i>	<i>S. equinus</i> , <i>S. gallolyticus</i>	Endocarditis Sepsis	Linked to colonic carcinoma	Riyaz et al. (2016)
Diagnosis Prognosis Epidemiology	<i>Vibrio cholerae</i>	<i>Vibrio mimicus</i>	Gastroenteritis	Enteritis vs. cholera; 01/0139 vs. non-01	Thompson et al. (2008)

SSTI, skin and soft tissue infections.

1990s standalone molecular platforms were introduced involving the genetic sequencing of housekeeping genes such as 16S (Janda and Abbott, 2007). Today, there are literally dozens of commercially available tests that can identify single species or targeted groups of bacteria.

Obviously the more state-of-the-art analytical instrumentation employing molecular strategies offers a more precise and definitive identification of bacteria than does conventional testing platforms developed years ago. In the case of bacterial identifications, the accuracy of such systems ranges from spot tests $\rightarrow$ commercial panels $\rightarrow$ PCR $\rightarrow$ Matrix-Assisted Laser

Fig. 1 Technologic Developments in the Identification of Bacteria (1960–2010).

Desorption Ionization-Time-of-Flight Mass Spectrometry (MALDI-TOF) → 16S gene sequencing → Whole Genome Sequencing (WGS). However, the choice of identification systems used in each laboratory can vary significantly because of a number of factors.

General principles of testing strategies

The “gold standard” for laboratory testing is diagnostic accuracy which theoretically implies 100% sensitivity and specificity. Other principles that need to be considered in evaluating the usefulness of any diagnostic test for infectious diseases include performance, operational characteristics, and price versus clinical impact (Banoo et al., 2006; Cantón et al., 2017). In the broader sense, laboratory tests are only one of three components needed to accurately diagnose a patient’s illness. These components are analytical validity (lab testing), clinical validity, and clinical utility (Wolk, 2020).

The choice in testing methodologies used in clinical laboratories to identify bacteria must be counterbalanced by the analytical validity of each assay against a number of competing factors including size and staffing of the microbiology laboratory and type of medical or public health facility. Sample testing volumes can vary dramatically from ~10,000 to more than half a million/year. These values do not even include significant variations in numbers or types of tests offered. These driving forces will dictate to a great extent options available for the type of test formats than can be used in particular situations. A second competing factor is cost. The cost of tests useful in identifying bacteria can range from a few cents for phenotypic assays to >\$100 for a single multiplex PCR cassette. Costs are even much higher for WGS. While a test itself can cost pennies to perform (MALDI-TOF), the initial capital investment can be expensive as the cost of instrumentation can exceed \$200,000. As the accuracy of a definitive test for bacterial identification increases with the use of molecular platforms so do the costs.

Regulations

In the United States (USA) the identification of bacteria in the clinical laboratory in most instances is judged to be a high-complexity test. Identification of bacteria leading to a disease-specific condition, patient prognosis, or treatment falls under the Clinical Laboratory Improvement Amendments (CLIA) of 2003 (Anderson et al., 2009). CLIA is administered by Centers for Medicare and Medicaid (Baltimore MD). CLIA regulates the identification of bacteria as it relates to patient care and treatment but does not regulate epidemiologic investigation or environmental surveillance (Table 1). CLIA certifies diagnostic laboratories in the US by monitoring testing practices, quality control, proficiency testing, and test validation among other things.

The second category of testing regulations for bacterial identification involves medical devices. Devices used for the diagnosis of infectious diseases are reviewed by the Division of Microbiology Devices, Center for Devices and Radiological Health, Food and Drug Administration (FDA) (Shawar and Weissfeld, 2011). Commercial-based tests are rigorously tested and evaluated by the FDA prior to formal approval. The category of test complexity (waived, moderate, high) is determined by the evaluation of seven factors which include knowledge needed, training and experience, reagents and materials preparation, characteristics of operational steps, calibration, quality control, and proficiency testing materials, test system troubleshooting and equipment maintenance, and interpretation and judgment required.

A key area not considered before the advent of many molecular testing platforms are standalone tests, also known as “home brews” which are not FDA approved. Such technologies were previously classified as in vitro diagnostics by the FDA whose use and development were operated within a single clinical laboratory facility (Genzen, 2019). One example of this type of technology

would be genome sequencing which is now classified by the FDA as Laboratory-Developed Tests or LDT when used in diagnostic settings. A long-term resolution regarding oversight of LDTs is uncertain (Genzen, 2019). Currently to use such a test or to modify another test (e.g., enhance database) means that such an assay automatically defaults to high-complexity testing. Extensive validations to meet CLIA requirements is required. Two examples of the validation of Illumina platforms, one designed to meet CLIA requirements, have been recently published (Kozyreva et al., 2017; Arnold et al., 2018).

Bacterial identification and modern molecular taxonomy

The final identification of a bacterium associated with human infections is intimately linked to the field of bacterial taxonomy. The appropriate use of bacterial taxonomy is how we communicate worldwide regarding classic or emergent illnesses or disease syndromes, species-associated clinical manifestations, appropriate medical intervention including antimicrobial therapy, and epidemiologic investigations ranging from outbreaks to global pandemics (Janda, 2021). The simple assignment of the appropriate scientific name (genus and species) to a pathogenic bacterium immediately also allows for a historical review of medical and scientific literature regarding disease symptoms, treatment, prognosis, and infection control-related aspects. No matter what system is used to provide a final bacterial identification, the key to its usefulness and function is the correct placement of a scientific name on the infectious agent in question.

Innovative molecular methods have impacted the field of modern taxonomy such that the number of proposed taxa has exploded over the past 15 years with over one thousand new species often described on an annual basis (Janda, 2017). FDA approved commercial identification systems have internally constructed databases for bacteria tested and identified on each system which allow for genus and species recognition. However, in the case of non-FDA approved molecular systems the construction of databases may be proprietary in nature and of unknown phylogenetic range and depth while other platforms producing sequence identifications are linked to public or private databases such as GenBank. The end result is that both FDA and non-FDA approved systems used to provide bacterial identifications have a difficult time keeping up with a rapidly evolving prokaryotic taxonomy.

Identifications need to be up-to-date and conform to present rules and regulations concerning bacterial nomenclature and taxonomy. The List of Prokaryotic names with Standing in Nomenclature (LPSN) is the most comprehensive source for all bacterial names. It has recently been acquired by Leibniz Institute DSMZ—German collection of Microorganisms and Cell Cultures GmbH (Parte et al., 2020). For clinical microbiology, two journals (*Diagnostic Microbiology and Infectious Diseases*, *Journal of Clinical Microbiology*) provide periodic updates on new taxa and classification changes associated with bacteria isolated from clinical samples (Janda, 2017; Munson and Carroll, 2021).

Laboratory decisions regarding test selection and menus

Emerging trends

The modern era for diagnostic microbiology has witnessed a number of increasingly important trends concerning the identification of bacteria in the clinical laboratory. These emerging trends can be summarized as follows: (1) A gradual transition from conventional testing formats to molecular-based platforms as depicted in Fig. 1 (Laupland and Valiquette, 2013). Such technologies include targeted- or multiplex PCR, loop-mediated isothermal amplification, 16S gene sequencing, mass spectrometry and WGS (Wolk and Dunne, 2011; Mitsuma et al., 2013; Laupland and Valiquette, 2013; Li et al., 2017). Driving forces behind implementation of these newer technologies in the diagnostic laboratory are a more rapid and definitive identification of bacteria; (2) Automation in clinical microbiology is slowly evolving from inoculation systems to partial or completely automated systems for bacteriology (Croxatto et al., 2016; Leo et al., 2020). European labs have been innovators in the emergence of this technology but it is now being implemented in some US laboratories as well; (3) An increasing trend towards higher sample volume requests most likely due to molecular assays, increasingly limited laboratory budgets, and a greater percentage of lab expenditure versus overall medical costs. In the United States, estimated healthcare figures for 2018 totaled \$4.4 trillion dollars which is more than 20% of gross domestic product (Ricaldi et al., 2014). A much earlier figure from 2002 found laboratory expenses at \$2.5 billion with an annual growth rate of 10% (Ricaldi et al., 2014). Precipitously high lab costs have led to financial constraints by limiting laboratory budgets and management initiatives for “lean microbiology” (Samuel and Novak-Weekly, 2014); (4) Concurrent to the expansion in molecular testing methods has been potential increases in federal or national regulatory oversight of in vitro devices commonly referred to as LDTs (Dunne Jr, 2011; Genzen et al., 2017; Genzen, 2019). Such regulations could impact how and if LDTs can be used in a clinical environment (Bank et al., 2020).

Laboratory logistics

With the increasing demand on laboratories for more accurate and rapid testing versus increasing test requests, dwindling budgets, and limited peripheral resources the laboratory director and staff are faced with a series of complex and competing issues. These issues dictate to a large extent what methods for identifying bacteria can be introduced into the clinical laboratory. In the United States, federal testing requirements under CLIA are intertwined with state or university-required licensure or certifications such as those provided by the American Society of Clinical Pathology to provide high complexity testing. These personnel requirements are

offset by fewer hospitals or universities offering laboratory-based programs for certification which translates into fewer certified personnel entering the workforce (Dunne, 2011; Croxatto et al., 2016). Other notable factors that dictate the choice of testing algorithms include test reimbursement rates, laboratory space, staffing and hours of operation, types of clinical and anatomic samples received, and patient population served (Samuel and Novak-Weekly, 2014).

Clinical factors

A number of clinical factors impact the selection of test menus for the identification of bacteria. These factors are outside the realm and control of clinical laboratories. The introduction of rapid molecular diagnostic tests to quickly identify bacteria causing bloodstream infections (BSIs) allows for improved patient care by changing from empirical therapy to species-directed chemotherapeutic intervention (Wu et al., 2020). Use of such technology also leads to more accurate BSI diagnosis, patient care, reducing timelines for effective therapy, and cost-effectiveness (Sakarikou et al., 2018; Wu et al., 2020; Briggs et al., 2021). Such innovative developments or methods drive testing volumes upward with associated costs impacting the laboratories that provide such resources.

Laboratory tests, which include the identification of pathogenic bacteria in the clinical microbiology laboratory, are the main data source that supports or influences physician decisions on patient care (Bindraban et al., 2018; Ekblom and Peterson, 2018). The oft-quoted but poorly substantiated figure of 70% refers to the percentage of clinical decisions made in medical practice based upon test results (Samuel and Novak-Weekly, 2014; Bindraban et al., 2018; Hicks et al., 2021). With the advent of rapid molecular tests this has led to a staggering increase in test requests which impacts the microbiology laboratory. Data suggests, however, that at least 20% of test requests are either not needed or not appropriate for a particular clinical picture (Bindraban et al., 2018; Cadamuro et al., 2018). These contributing factors again raise the financial costs incurred by the diagnostic laboratory. Reducing test utilization is a key component of helping to maximize the diversity and number of tests a microbiology lab can offer by reducing both the type of test selected and test volume (Ricaldi et al., 2014).

Bacterial identification: Test categories and strategies

There is presently a large litany of tests, technologies, and devices that have been developed over the past 40-odd years useful in providing a definitive identification for clinically significant bacteria (Wolk and Dunne, 2011; Laupland and Valiquette, 2013; Tshikhudo et al., 2013; Li et al., 2017; Fairfax et al., 2018). Many systems are no longer in general use as they become outdated by newer technology, cost factors, or clinical applications. Bacterial identification strategies have been broken down into four broad categories (Fig. 2). These include rapid tests, phenotypic or biochemical analyses, PCR-based assays, and molecular platforms which include mass spectrometry. Each of these categories has witnessed technologic developments of newer and more innovative approaches to the identification of pathogens over time (Table 3). PCR tests are separated out as many of these assays have been commercially developed and FDA-approved in contrast to most other molecular platforms. This section will cover those tests that presently have found the greatest widespread application in the field of bacterial identification worldwide.

Fig. 2 Groups of Tests Currently Used in Bacterial Identification in Laboratories.

Table 3 Identification of bacteria by standard and advanced methods.

Type of test		Phenotypic	Rapid diagnostic tests	PCR	Molecular
Clinical applications	Standard methods	• Conventional (TSI, LDC, etc.) • Biochemical test strips (API 20E)	• Spot assays (indole, MUG, PYR, etc.) • Gram stain • Hemolysis (BAP)	• Monoplex PCR	• Sanger sequencing
	Advanced applications	• Combo ID/AST plates (MicroScan, VITEK, Phoenix) • Accelerate PhenoTest • Carbon Source Utilization • FAME • Latex agglutination assays • ELISA	• Lateral flow immunoassays • Dipsticks	• Multiplex PCR • Syndromic panels (GI, RTI)	• MALDI-TOF • 16S rDNA gene sequencing • pyrosequencing • WGS

AST, antimicrobial susceptibility testing; BAP, blood agar plate; ID, identification; ELISA, enzyme-linked immunosorbent assay; FAME, fatty acid methyl ester; GI, gastrointestinal; LDC, lysine decarboxylase; MALDI-TOF, Matrix-Assisted Laser Desorption Ionization-Time-of-Flight Mass Spectrometry; MUG, 4-methylumbelliferyl- β -D-glucuronide; PYR, pyrrolidonyl aminopeptidase; PCR, polymerase chain reaction; RTI, respiratory tract infection; TSI, triple sugar iron; WGS, whole genome sequencing.

Rapid assays

There are many clinical and epidemiologic settings where a rapid test may be needed or warranted. Most rapid tests are either a general biochemical test used to screen or identify a certain bacterial species, a species-specific rapid immunologic or molecular test (<2 h) in clinical situations, or a field test where a traditional laboratory workup is not practical. Almost all of these tests are species-specific excluding syndromic panels that are discussed elsewhere.

Although out of vogue, standalone or “spot” biochemical tests can be used with a fairly high degree of accuracy to identify a limited but significant set of commonly encountered bacteria. The advantages of such tests are that they are extremely cost-effective, can generate a final identification in just a few minutes, and have an overall accuracy of at least 95%. Caveats associated with such testing require a pure culture, a microbiologist knowledgeable regarding colonial morphology and test reactions, and the understanding that a misidentification using such a scheme is unlikely to impact patient care (York, 1999). Successful multi-laboratory validations of individual tests, such as the spot indole, L-pyrrolidonyl- β -naphthylamide (PYR), to correctly identify *E. coli* show an error rate of 0.3% (York et al., 2000). Collective guidelines for use of abbreviated or rapid testing schemes have subsequently been published (Baron, 2001; CLSI, 2008).

Another standard test useful in the rapid detection of bacteria is the lateral flow immunoassay or LFIA (Andryukov, 2020). LFIA tests are relatively inexpensive, easy to read and can yield a final identification quickly. Bouzid et al. (2021) have recently reviewed the use of LFIA in the emergency department. Among bacterial species that can be rapidly identified correctly using LFIA are Group A streptococci, *Streptococcus pneumoniae*, *Legionella pneumophila*, and *Treponema pallidum*. A disadvantage of this system is a lack of a viable culture.

Rapid tests are also useful for many orphan diseases or for important public health pathogens that require an immediate diagnosis. Such is the case of *Vibrio cholerae*, the causative agent of epidemic or pandemic cholera. Many cases of cholera occur in remote locations of Africa or Asia where it is extremely difficult to get a specimen transported promptly to a clinical laboratory. Such delays can impact the health of an infected person and can impact the spread to others through contaminated food or water. Immunochromatographic tests have been developed to rapidly detect cholera on-site allowing for immediate public health intervention. One such test, the VC[®] Rapid Dipstick (Span Diagnostics, India) can detect *V. cholerae* in stools directly (or after a 4–6 h incubation in alkaline peptone water enrichment) within 15–30 min (Harris et al., 2009; Ontweka et al., 2016). Enrichment cultures showed a sensitivity of 100% (Ontweka et al., 2016). The test detects both *V. cholerae* O1 and O139 serotypes.

Phenotypic assays

Despite being the oldest of the current testing venues for bacterial identifications in the clinical laboratory, phenotypic methods remain the mainstay for most laboratories (Laupland and Valiquette, 2013; Li et al., 2017; Chakraborty and Doijad, 2018). Biochemical tests are by far the most commonly employed method by which most laboratories render final identifications. These collective systems share a number of distinct advantages in common including they are low-cost, easy to perform, and are highly accurate in the identification of established genera and species. In contrast, such systems have a number of inherent disadvantages including (1) delayed reporting times of 1–3 days for final identifications, (2) a pure culture is required such that identifications cannot be directly made from anatomical specimens such as blood, (3) test results that can theoretically be influenced by growth medium or environmental conditions, and (4) commercially-associated databases which cannot keep up with an expanding list of newly described taxa (Wolk and Dunne, 2011; Janda, 2017; Tshikhudo et al., 2013; Li et al., 2017).

Manual microidentification systems

The “Grandfather” of phenotypic identification systems is the API 20E strip (bioMérieux, Durham NC) and its progeny such as the API NH and Rapid ID 32 A. First introduced in the 1970s it miniaturized standard tests into microcapsules. In the case of API 20E, the strip consists of 20 tests (plus a manual oxidase test) that generates a 7-digit code based upon 21 reactions after an 18 h incubation. Inputting this code into the APIWEB™ database yields a final identification. This strip has now been used for over 40 years in clinical laboratories. Another such system is the BBL Crystal Enteric/Nonfermenter system (Becton, Dickinson and Company, Sparks MD). The Crystal E/NF panel contains 29 dehydrated test substrates plus a control. Like API it produces a 10-digit code leading to an identification. While both systems provide good to excellent identifications for common bacteria, they suffer from several disadvantages in addition to those noted above. Foremost among these is a bacterial identification without an accompanying antimicrobial susceptibility profile. Secondly, as in the case of the API 20E strip the test configuration has not changed in 40 years. Since this test invention preceded many of the bacterial species described since 1980 the battery of tests on the strip may not be ideal for more recently described taxa.

Automated microidentification combo panels

Offspring of manual identification systems were commercially developed during the late 1970s and early 1980s. These “Expert Systems” rely on the use of artificial intelligence with clinical applications useful for diagnostic microbiology (Winstanley and Courvalin, 2011). Among the major new features of these systems were (1) the development of a combination (combo) panels providing both an identification (ID) and antimicrobial susceptibility (AST) profile concurrently for each bacterium tested, (2) fully automated systems including reading of test results and test interpretation, thereby eliminating manual reader bias and errors, (3) expanded panels with biochemical tests to more accurately identify newly described infectious agents, (4) enhanced commercial databases for both ID and AST, and (5) periodic updated versions of software and peripherals (Winstanley and Courvalin, 2011; Li et al., 2017). Commercially automated systems commonly used on a global basis included the BD Phoenix (Hunt Valley MD), bioMérieux VITEK 2 (Durham NC), and DxM MicroScan Walkaway (Beckman Coulter Inc., Carlsbad CA). These automated systems have been the primary “workhorses” in diagnostic labs for years. However, they still lack as rapid a turnaround time (ID and AST) as physicians would like for patient care.

Bloodstream (BSIs) are one of the most serious and life-threatening complications associated with hospitalization. BSIs represent the second largest cause of healthcare-associated mortality in USA hospitals (Briggs et al., 2021). To decrease the incidence of negative outcomes of BSIs and associated costs of medical management requires more rapid system of bacterial ID and AST to detect cases of bacteremia and to revise medical management and empirical therapy as quickly as possible (Sakarikou et al., 2018; Özenci and Rossolini, 2019).

Recently, a more rapid bacterial identification and susceptibility testing system that can be used directly on positive blood cultures was FDA-approved in 2017. The Accelerate PhenoTest™ system (Accelerate Diagnostics Inc., Tucson AZ) relies on fluorescent *in situ* hybridization or FISH with morphokinetic cellular analysis to generate a final bacterial ID and AST result in 2 and 7 h respectively. When compared to standard methods, the PhenoTest™ system exhibited an identification specificity of between 91% and 99.5% for organisms in their database and a sensitivity of 95.6% (Marschal et al., 2017; Charnot-Katsikas et al., 2018; Ullberg and Özenci, 2020). Overall categorical agreement for AST was 95.5–96.4% with very major errors reported at 1% (Marschal et al., 2017; Charnot-Katsikas et al., 2018). The Accelerate system also reduced the time to ID by 23–27 h and AST results by >40 h (Marschal et al., 2017; Charnot-Katsikas et al., 2018). The system presently has difficulty with streptococcal species and coagulase-negative staphylococci as well as some less frequently encountered gram-negative bacteria (Marschal et al., 2017; Ullberg and Özenci, 2020).

PCR

The invention of PCR technology by Kary Mullis, for which he won the Nobel Prize in 1993, shepherded in the modern molecular era in the diagnostic microbiology laboratory (Fairfax et al., 2018). PCR technology allows for the amplification of DNA (genes) through a series of thermocycling reactions coupled to a heat-stable DNA polymerase (Laupland and Valiquette, 2013). Amplified products (targets) can then be detected utilizing a number of different techniques including reverse transcriptase-PCR, transcription-mediated amplification, and nucleic acid sequence-based amplification (Li et al., 2017). Targeted DNA can be present as a pure culture, as an unknown pathogen embedded in soft tissue, or as part of complex microbial flora of the gastrointestinal or respiratory tracts as examples.

The advantages of PCR are many. PCR assays are rapid, precise, can have a broad range of targets (Laupland and Valiquette, 2013; AlMasoud et al., 2020). When utilized in a real-time PCR format the product can be detected and quantified over time. This can be incredibly useful when trying to detect which bacteria may be causing clinical disease in a complex microbial environment such as the respiratory tree. However, like all techniques it has several disadvantages. These disadvantages include knowing the sequence of a specific target, the inability to distinguish live and dead cells (DNA target), time-consuming, possible contamination issues, and requiring a certain amount of expertise (AlMasoud et al., 2020).

There are several basic configurations for PCR assays. The oldest and the forerunner of more modern-day applications is the monoplex reaction where the target is a single bacterial agent. Numerous commercial PCR tests have been developed in this configuration for bacterial diseases like *Mycobacterium tuberculosis* and *Neisseria gonorrhoeae*. Monoplex PCR reactions provide quicker definitive test results when compared to standard culture allowing for faster medical and public health intervention practices to be instituted. An offshoot on the monoplex reaction is the LDT. The advantage of an LDT is lower cost and the ability to detect orphan diseases which are not commercial practical for manufacture. LDTs are not FDA-approved and require validation to be used as an in vitro diagnostic device for human infections. Recently, multiplex PCR reactions, which are currently in vogue in clinical labs involve the use of multiple primers to detect multiple targets in different organisms. They offer several advantages that monoplex reactions cannot provide.

Syndromic PCR panels

The view of bacteria-associated infections has radically changed over the years from a one disease = one pathogen concept (diphtheria, tetanus) to a model of syndromic illnesses (gastroenteritis, bloodborne) which are caused by many different taxa. Over the past 10 years, commercial companies have developed and introduced multiple panels based upon multiplex PCR technology that can detect the many bacterial agents associated with a variety of syndromic diseases (Patel, 2016; Ramanan et al., 2018; Couturier and Dien Bard, 2019; Dien Bard and McElvania, 2020). The recognized leader in this field is BioFire (Salt Lake City, UT) which has received federal clearance for a number of diagnostic panels which can detect microorganisms including bacteria associated with syndromes such as gastroenteritis, septicemia, upper and lower respiratory tract infections, and meningitis/encephalitis.

While many different types of syndromic panels have been developed, the oldest of these panels involve the GI tract which in theory can serve as standalone-tests replacing conventional methodologies (Patel, 2016). A number of GI panels that are commercially available are listed in Table 4. All of these automated panels are based upon multiplex PCR technology but differ in their approaches, number and types of bacterial targets detected, whether the panels also detect viral and parasitic pathogens, and turnaround times. All systems essentially detect the four most common bacterial enteropathogens, namely *Campylobacter*, *Salmonella*, *Shigella* and STEC (Shiga toxin-producing *E. coli*). These are so-called “culture-independent” diagnostic tests (CIDT) as a final molecular identification of pathogens occurs without traditional culture. Thus, some of the major advantages of this technology (automation, ease-of-use, rapid identification) are partially counterbalanced by the fact that viable strains are not isolated, and therefore antimicrobial susceptibility and epidemiologic profiles cannot be generated (Janda, 2014).

There is considerable controversy regarding GI panels whether their use should be as a first-line testing option or of a more restricted nature (Schreckenberger and McAdam, 2015). On the positive side of first-line testing is the elimination of excessive technical time, maintenance and quality control of enteric media, and a rapid definitive diagnosis. On the negative side is test expense (>\$100/test), the limited number of enteric pathogens that require antimicrobial intervention, and the fact that many recognized enteropathogens are not detected by any of the commercially available panels. Table 5 lists some of the pluses and minuses of GI panels as they presently exist. Clinical situations where GI panels are useful include (1) individuals with severe dehydration, bloody diarrhea, colitis, or dysentery, (2) persons with subacute (14–28 days) or chronic diarrhea (>28 days) where the detection of enteroaggregative *E. coli* or *Plesiomonas* is entertained (3) for infectious agents that, if detected, require treatment

Table 4 Commercial syndromic panels to detect bacterial gastroenteritis.

Panel	Manufacturer	Targets		Time to Detection (hours)	FDA Approved
		Total ^a	Bacterial		
BioCode [®] Gastrointestinal Pathogen Panel	Applied BioCode (Santa Fe Springs, CA)	16	10	4	Yes
BD MAX [™] Enteric Bacterial Panel	BD Diagnostics (Sparks, MD)	4 (7) ^b	4 (7) ^b	3–3.5	Yes
EntericBio [®] Gastro Panel 2	Serosep (Limerick, Ireland)	6	4	3	No
FTD Bacterial Gastroenteritis	Siemens Healthcare (Erlangen, Germany)	7	7	6	No
FilmArray GI Panel	BioFire bioMérieux (Salt Lake City, UT)	22	13	1	Yes
ProGastro	Hologic Prodesse (San Diego, CA)	4	4	4	Yes
Seeplex [®] Diarrhea-B1 ACE Detection	Seegene (Seoul, South Korea)	5	5	9–10	No
Verigene [®] Enteric Pathogens	Luminex Corp. (Austin, TX)	8	6	2	Yes
XTAG GPP	Luminex Corp. (Austin, TX)	14	8	5	Yes

^aIncludes viruses and parasites.

Table 5 Advantages and disadvantages associated with gastrointestinal syndromic molecular panels.

PRO	CON
• Rapid final identification (hours) • Automated; ease of use • Standalone technology • Eliminates or reduces enteric media and technical time • Can detect multiple enteric pathogens simultaneously • Use may reduce the number of endoscopies and related procedures	• Expense (cost per test) • No viable culture for antimicrobial or epidemiologic profile • Potential false-positives • Targets of questionable clinical significance (e.g., <i>Clostridioides difficile</i>) • Many accepted enteropathogens not covered (<i>Aeromonas</i>, specific <i>Vibrio</i> species) • Multiplex GI testing useful only for specific subpopulations

(e.g., shigellosis), and (4) for epidemiologic purposes such as outbreaks (DuPont, 2009). Some of the clinical questions one needs to consider in the use of molecular tests are stressed in a recent commentary by Tarr et al. (2019).

From the laboratory perspective, a number of issues remain unresolved. One surprising finding has been the number of positive stools that contain 2 or more enteropathogens. In a study of traveller's diarrhea 75.8% of FilmArray GIP-positive samples contained multiple pathogens (Kutsuna et al., 2021). Other studies using the Luminex GPP found 56.2% of pediatric patients positive for enteropathogens while 24.2% of controls contained enteropathogens as well (Tilmanne et al., 2019). A question to be asked is what does this mean and how do you interpret such test results as a significant number of false-positives have been reported (Dien Bard and McElvania, 2020)? Contamination has also been a problem leading to false-positive test results on the FilmArray system for *Vibrio cholerae* O1 and *Yersinia enterocolitica*. How common this situation is, is not known but has led to some panel revisions by the manufacturer. Finally, one large study found that an enteropathogen could only be recovered (reflex culture) from 57% of CIDT-positive samples (Imdad et al., 2018). Such results if repeated in other investigations could have a severely negative impact on epidemiology and public health.

MALDI-TOF

One of the remarkable achievements in modern diagnostic microbiology has been the introduction of MALDI-TOF into the mainstream of clinical microbiology to rapidly identify pathogenic bacteria (Fairfax et al., 2018; Welker et al., 2019; Tsuchida et al., 2020). Unlike other molecular techniques, MALDI-TOF relies on proteomics and the characterization of bacterial proteins at the molecular level. The technique, developed and refined for diagnostic use over a quarter of a century (1975–2000), involves a laser that emits soft ionization which then transfers energy to a matrix containing bacteria eventually leading to protein ions for analysis (Wolk and Clark, 2018).

MALDI-TOF requires only a small sample of a pure bacterial colony spotted onto a metal plate allowed to dry before being overlaid with a crystalline matrix typically composed of either α -cyano-4-hydroxycinnamic acid or 4-chloro- α -cyanocinnamic acid (Patel, 2016; Wolk and Clark, 2018). Bacterial molecules (proteins) are subsequently desorbed by short laser pulses in a vacuum tube producing ionized proteins with a mass ranging from 20 to 100 kDa. The ionized proteins are then accelerated through a positively charge electrostatic field into an analyzer where a taxon's molecular protein fingerprint composed of individual mass spectra is compared to reference spectra in a database (Patel, 2016). In theory each microorganism produces a unique protein signature identifiable as a spectral fingerprint resolvable at the genus and species level.

MALDI-TOF has a wide range of potential medical applications including the diagnosis of both infectious and non-infectious conditions. Currently the primary role MALDI-TOF plays in a majority of clinical laboratories is in providing a final identification of clinically significant bacteria. Two MALDI-TOF systems have FDA approval in the United States. These are the VITEK[®] MS (bioMérieux, Marcy-l'Etoile, France) and the MALDI Biotyper[®] (Bruker Daltonics, Billerica, MA). These are the two leading mass spectrometry systems in use today. For laboratories and hospitals, they offer a number of distinct advantages including a definitive identification in <5 min (Patel, 2016; Fairfax et al., 2018), considerable material and labor saving, the potential to streamline early empirical therapy based upon a rapid diagnosis (Florio et al., 2018), and reduced length of stays for hospitalization with associated costs (Psaroulaki and Chochlakis, 2018). The two MALDI-TOF systems, while similar, differ in several aspects. The Biotyper[®] produces identification scores between 0 and 3 (Florio et al., 2018). A score of ≥ 2.0 indicates a high confidence in genus and species identification while a score of ≥ 1.7 to <2.0 suggests confidence to the genus level only. Scores below 1.7 are interpreted as "no identification." With the VITEK[®] MS a score is generated based upon a probability percentage. Percentages are color-coded with a green square >90% identity, a yellow triangle for 85–89.9% identity, and red circle for <85%. Identifications with a green square are considered reliable while those with a yellow triangle are considered acceptable. These systems also differ in their respective databases and construction of diagnostic algorithms (Patel, 2016; Tsuchida et al., 2020). Several other mass spectrometer systems are available for the identification of bacteria that are not FDA approved. These include Autof MS1000 (Autobio Diagnostics Co. Ltd, Zhengzhou, China) and ASTA MicroIDSys (ASTA, Suwon, Korea).

As of 2019, there were more than 3,000 published articles on "MALDI-TOF and microbiology" listed on PubMed which are beyond the scope of this section for discussion (Angeletti and Ciccuzzi, 2019). Both FDA-approved MALDI-TOF systems provide a high percentage of correct identifications for many common bacteria and some more difficult-to-identify species (Levesque et al.,

2015). While the cost-per-test is remarkably small, the initial cost to purchase a system is sizable running in excess of \$200,000 USD. This figure does not include such items as maintenance contracts and associated reagents. The cost of such technology actually precludes many smaller to moderate-sized laboratories from adopting this technology (Welker et al., 2019). Hopefully, the cost will decline in the future. Other factors to consider in whether to purchase a MALDI-TOF system or not include the number and types of bacteria that require a molecular identification and the patient population served.

Despite its common use in laboratory settings, MALDI-TOF is still in the developmental stage as a diagnostic tool. How good a final identification is depends upon how well each MALDI-TOF system's database is curated and how extensive and diverse is the collection of strains used to represent a single taxon (genomospecies). Additionally, a number of reports have repeatedly documented that one or both FDA-approved systems have issues identifying species or phenotypically similar groups or complexes. These taxa include mycobacteria, *Streptococcus pneumoniae* and the *Streptococcus oralis/mitis* group, *Listeria* spp., *Enterobacter* spp., some strains of *Stenotrophomonas maltophilia* and members of the *Burkholderia* and *Acinetobacter baumannii* complexes (Florio et al., 2018; Oviaño and Rodríguez-Sánchez, 2020). Of particular importance is the resolution of *Shigella* species from one another and their separation from *Escherichia coli* since this entire group constitutes a single genetic species although their separation has important medical as well as public health implications.

At the time of writing, the VITEK® MS system included approximately 400 bacterial species in their database. Some organisms that this system could not previously identify (*Brucella*, *Elizabethkingia anophelis*) have been recently added and are FDA-approved. Many other taxa are currently not available, particularly those that are less frequently encountered in the clinical environment. This requires development of an in-house custom library through supplementation of the existing database with additional spectral fingerprints from different taxa. An interesting letter by Pandey et al. (2019) detailed how issues occurred in regards to bacterial identifications after introduction of the MALDI Biotyper® into their laboratory as the primary method of identification for ~90% of cultures. The laboratory found a number of serious errors including where *Neisseria meningitidis* was misidentified as *N. gonorrhoeae*. Other issues noted were the separation of *Salmonella* and *Citrobacter* species and species-level identifications for *Klebsiella variicola* and *Haemophilus* spp. The authors now use conventional tests in many of these scenarios. Collectively, this data strongly suggests that MALDI-TOF is not at present a “standalone” instrumentation that can be used unequivocally to identify all bacteria in the laboratory. Rather MALDI-TOF can be a useful adjunct to a bacterial identification scheme encompassing more than one technique.

16S rDNA gene sequencing

A standard technique often seen in moderate- to larger-sized diagnostic laboratories since the mid- to late-1990s is 16S rDNA gene sequencing for the definitive identification of bacteria. This technique has a number of advantages over phenotypic methods. Besides being based upon nucleic acid sequences instead of the phenotypic expression of genes, the method is highly accurate, quantifiable, and objective and can be used to identify rare bacteria with atypical biochemical profiles, slow-growing organisms, and the identification of novel species (Petti, 2007; Woo et al., 2008). Furthermore, broad-range 16S rDNA PCR has the capability to directly identify bacteria to genus and species from clinical samples without culture (Akram et al., 2017). This can be medically important in culture-negative cases and to target antimicrobial therapy directly against a particular microbe. Finally, 16S gene sequence analysis has often been used as an arbitrator in final bacterial identifications when two or more other phenotypic or molecular methods yield conflicting results (Pandey et al., 2019). In many clinical laboratories it is now considered to be the “gold standard” in routine bacterial identifications (Laupland and Valiquette, 2013).

The 16S housekeeping gene encodes for a portion of the 30S ribosome (Petti, 2007). The full sequence is approximately 1500 bp in length (Janda and Abbott, 2007). Due to the fact that all bacteria possess at least 1–15 rRNA operons with most species (>80%) possessing more than one, it provides an excellent target for gene amplification and sequencing (Espejo and Plaza, 2018). The 16S gene is composed of both conserved and hypervariable regions, the latter designated V1–V9 (Tshikhudo et al., 2013). The variable regions provide for sequence diversity in regards to taxonomic identification. An advantage of the 16S gene is that because of its overall functional importance to all bacteria it is highly conserved on an evolutionary scale although “drift” in some species has been detected.

Standard analysis of the 16S rDNA gene employs Sanger sequencing (chain terminating dideoxynucleotides) although 16S rDNA next-generation sequencing is also quite common (Rizal et al., 2020). The sequential process includes DNA extraction, PCR amplification with universal primers of the 16S gene, purification, and then subsequent 16S sequencing (Laupland and Valiquette, 2013). Sequencing and final bacterial identifications can be achieved using a commercial product with included database or by importing sequence results into public or private databases such as GenBank or the Ribosomal Database Project. The most common commercial system used is the MicroSEQ™ microbial identification system (Thermo Fisher, Waltham, MA). MicroSEQ™ databases range in size from 1,400 to over 7,000 entries. The MicroSEQ™ system is sold as a “Research Use Only” application and thus requires validation for diagnostic use in the United States.

Final bacterial identifications based upon 16S rDNA sequencing are determined by % similarity or % divergence of the test strain when compared to reference sequences such as the type strain. While no single value is universally recognized for a 16S species match, a threshold value above 98.7% is generally accepted as a minimum requirement for species identification (Rossi-Tamisier et al., 2015; Janda, 2018). In most instance values above 99% sequence similarities are used clinically for species identification. Genera can be assigned when a sequence similarity score of $\geq 97\%$ is obtained. Various other algorithms have been proposed for assigning genus and species names to medically important bacteria (Park et al., 2015). Most bacteria can be correctly identified to

species from partial (500 bp, V1–V3) rather than full (1500 bp) 16S sequences (Hong and Farrance, 2015). However, no single hypervariable region can distinguish all medically important bacterial species (Chakravorty et al., 2007). In some instances, species can only be identified by sequencing the entire 1500 bp gene (Hong and Farrance, 2015). For laboratories that only occasionally need more definitive identifications via 16S, a variety of companies offer commercial services for around \$50 USD an isolate.

As in the case of MALDI-TOF, 16S rDNA gene sequencing has a number of limitations. 16S platforms are not easily amenable to lower- to middle-income countries or smaller to moderate-size clinical labs in the United States when costs are compared to routine culture and biochemical identification (Rizal et al., 2020). Due to the fact that ribosomal genes are highly conserved because of their essential cellular function, their ability to taxonomically distinguish between two closely related species can be limited (Janda and Abbott, 2007; Rossi-Tamisier et al., 2015). Common species or groups containing many members difficult to resolve by 16S include the family *Enterobacteriaceae*, the *Streptococcus mitis* group, some *Campylobacter* species, mycobacteria, and complex members belonging to the genus *Burkholderia* as examples (Srinivasan et al., 2015; Hong and Farrance, 2015; Rossi-Tamisier et al., 2015; Rizal et al., 2020; Church et al., 2020). Improved species identification for some groups such as the *Enterobacteriaceae* can be achieved using *dnaJ* sequencing (McLean et al., 2019; Rizal et al., 2020). Similarity values produced from 16S rDNA sequencing are also subject to misinterpretation. The highest 16S similarity match to a test strain does not necessarily imply genetic identity. DNA-DNA hybridization data on select species does not always correlate with 16S values and when multiple 16S matches or scores deviate from each other by <0.5%, a final identification is always tentative unless supported by other methods (Janda and Abbott, 2007; Park et al., 2015). For a comprehensive and exhaustive overview of the role 16S plays in the routine identification of pathogenic bacteria the reader is encouraged to consult the authoritative review of Church et al. (2020). The review covers various aspects of 16S rDNA gene sequencing including sequence analysis, troubleshooting technical problems, and the identification of many major groups of bacteria causing infectious diseases (Church et al., 2020).

Next-generation sequencing (NGS)

Until the early 2000s, Sanger capillary sequencing, also known as dye- or chain-terminator or first-generation sequencing, was the backbone platform for the sequencing of bacterial genomes in academic and clinical settings (Tshikhudo et al., 2013; Besser et al., 2018). Sanger capillary sequencing began to be replaced post-2005 by NGS. NGS is primarily defined as a high-throughput method where millions of DNA fragments can be sequenced in parallel simultaneously and independently (Mitchell and Simmer, 2019). The earliest of these NGS technologies to have a diagnostic application in the microbiology laboratory was pyrosequencing with the introduction of the Roche 454 Life Sciences platform (Glenn, 2011; Besser et al., 2018). Pyrosequencing is often called second-generation sequencing since the platform requires amplification of the template molecules prior to sequencing (Glenn, 2011). This method of sequencing-by-synthesis involves the detection of released pyrophosphate (PPi) during DNA synthesis (Harrington et al., 2013). As opposed to the Sanger method where longer (500–1000 bp) DNA sequences are produced, pyrosequencing works with shorter reads of 50–400 bp (Besser et al., 2018). Pyrosequencing was found to be especially useful in the identification of certain groups of bacteria including mycobacteria. Unfortunately, this technology went out of vogue and the 454 Life Sciences platform was discontinued by Roche in 2015 (Rizal et al., 2020).

Third-generation sequencing involves platforms that directly sequence individual DNA molecules (Glenn, 2011). NGS involves two separate steps in this overall method, namely a “wet” process involving the actual preparation and sequencing of a bacterial strain and a “dry” process of bioinformatics analysis (Rosen et al., 2018). Excluding first-generation sequencing, NGS relies on one of three different basic technologies including pyrosequencing, reversible terminator chemistry, and sequence-by-ligation (Tshikhudo et al., 2013). Detection methods also vary. The premier system at present in this category is the Illumina platform (Illumina Inc., San Diego, CA) in which sequencing occurs by synthesis of the complementary strand with fluorescent-based detection of reversibly blocked terminator nucleotides; this platform has similarities to the Sanger approach (Tshikhudo et al., 2013; Besser et al., 2018). Illumina Inc. produces a series of benchtop sequencers (NextSeq 550, iSeq100) with different applications and capabilities and which vary in cost, throughput size, run times, maximum reads per run, and maximum read length. Other popular systems include the IonTorrent (Thermo Fisher, Waltham, MA) and PacBio RS II platforms (Pacific Biosciences) (Menlo Park, CA). The IonTorrent detection system involves solid state pH meters measuring H⁺ release during DNA polymerization. The MiniON system (Nanopore, Oxford, United Kingdom) is a long-read sequencing platform that offers low-cost sequencing and portable real-time devices for both DNA and RNA analysis. All of these systems differ in certain processes but follow a general workflow schema of DNA extraction → library preparation → template preparation → and automated sequencing bp (Besser et al., 2018).

NGS offers three main advantages to microbiologists in the identification and sequencing of bacteria over previous technologies which are high-speed, high throughput, and greater discriminatory power (Fairfax et al., 2018; Rosen et al., 2018). There are three currently useful applications of NGS which include WGS, targeted NGS, and metagenomic analysis (Mitchell and Simmer, 2019). WGS is the application that fits into the potential workflow of diagnostic laboratories. Presently, the primary use of NGS/WGS has been in the area of molecular epidemiology and the ability to track and identify outbreaks of infection associated with varying genotypes (Tagini and Greub, 2017; Fairfax et al., 2018; Besser et al., 2018; Mitchell and Simmer, 2019; Boers et al., 2019). Other current uses include detection of virulence characteristics and novel resistance determinants, fingerprinting, and the potential detection and identification of taxa in vivo or those that are difficult to grow in vitro. It has also been shown that full genome sequences with average nucleotide identity values of ≥95% correlate with species identity by other standard methods including 70% relatedness by DDH and >99% 16S sequence similarity. However, whether or not WGS could ever be used in a routine diagnostic application is questionable.

WGS is not without issues. The cost of any of these platforms can be sizeable with minimum costs ranging for a single whole genome sequence from \$120–\$250 USD or more. WGS is also set up for batch testing, not on a case-by-case basis such as needed in hospital settings (Rosen et al., 2018). Long reads with newer third-generation platforms are prone to error rates of 11–15% so there are tradeoffs between use of longer and shorter reads (Besser et al., 2018). Unlike many other laboratory tests, WGS requires dedicated staff for both the “wet” and “dry” portions as results are not simply “cookbook” in nature but require professional interpretation. Run times can also vary from 19 to 65 h depending upon the platform used (Rosen et al., 2018). Finally, WGS is not FDA approved which means extensive validation studies are needed (Kozyreva et al., 2017; Arnold et al., 2018). How proficiency testing, quality assurance and quality control practices are intertwined with testing is also problematic (Rosen et al., 2018). Considerable improvements are still need to be made for WGS to logistically fit into the clinical laboratory workflow.

Bacterial identification—ongoing issues

No system is perfect

One of the cardinal tenets of bacterial identifications is that no system is foolproof and errors occur. The literature is replete with case reports and comparative studies where either a non-molecular or molecular identification system has misidentified an important pathogen (Poonawala et al., 2018; Pandey et al., 2019; Mesa-Radiilla et al., 2019; Tarini et al., 2019; Sukhum et al., 2021). Some of the common groups often misidentified by multiple systems include *Neisseria gonorrhoeae*—*Neisseria meningitidis*, *Brucella*, *Acinetobacter baumannii* complex, *Burkholderia pseudomallei*, and the *Streptococcus mitis* group. In many instances such misidentification has enormous medical or public health consequences.

Whatever system is chosen by any laboratory as the primary method for bacterial identification it needs to come with the realization that it will at least occasionally yield incorrect identification results. Labs need to be aware of the major taxa each system has problems providing correct identifications for. As a result, each laboratory needs to have a backup system that is substantially different in methodology to provide a correct identification when needed. Difficult-to-identify bacteria can also be submitted to commercial or reference centers for final identifications by more sophisticated methodologies.

Databases

A less well appreciated problems facing labs is the composition of databases attached to commercial products. It is well known that the degree public or private databases are curated varies considerably (Janda and Abbott, 2007). This is particularly true for 16S data as many databases contain unidentified or poorly annotated sequences (Boers et al., 2019). A United Kingdom study found at least 5% of the 16S entries in the Ribosomal Database Project to contain substantial errors with at least 14% of these being unidentified sequencing errors (Ashelford et al., 2005). Another study found errors in the identification of *Pseudomonas* genomes at the rank of species (Tran et al., 2017). A 2020 investigation of *P. fluorescens* sequence data deposited in GenBank determined that all 28 strains were incorrectly identified to species when deposited (Morimoto et al., 2020). These same authors found similar results when *P. putida* strains were analyzed. Collective findings suggest that whatever system is used to identify bacteria the ability to generate a correct final identification is dependent upon how well the databases used is curated and updated. Sequence comparisons should always be to type strains or reference strains where DNA-DNA relatedness values are known.

An expanding bacterial taxonomy

There are now over 20,000 validly published bacterial names in the scientific literature and these numbers continue to rise (Pallen et al., 2021). While many of these newly proposed species are of environmental origin, a sizeable number continue to be recovered from clinical samples whether as infectious agents or colonizers of mucosal surfaces. The rapid expansion in species presents several problems. First, commercial products (FDA-approved or not approved) will have a great deal of difficulty keeping pace with taxonomic proposals and potentially incorporating some of these species into databases. This becomes even more difficult when the cumulative number of known strains per taxon is <25. How well these species are curated is another issue. Finally, these changes present numerous issues regarding whether or not modern bacterial taxonomy is relevant to clinical microbiologists (Janda, 2018).

Introduction

Within clinical mycology we face important challenges, because the fungal species that cause diseases are increasingly numerous and diverse. Diagnosing these diseases is a complex task that requires a series of classical tests, which despite continuous changes and advances in new methodologies, continue to be very useful in the routine microbiology laboratory. To make a good diagnosis, the coordinated action of the physician and the laboratory professional is essential, and the latter must have experience and knowledge to confirm or exclude a fungal etiology.

Conventional microbiological diagnosis of fungal diseases

This diagnosis is based mainly on the direct microscopic study of clinical samples and the fungi isolation by culture in artificial media. The first allows the observation of the fungus morphological structures in the sample, together with other elements that show the presence or absence of an inflammatory response. The second allows the identification of the fungus. Both steps are essential to establish the etiology of the fungal disease and depend on the collection of a clinical sample in optimal conditions, followed by its adequate handling, conservation and transport to the microbiology laboratory.

Direct microscopic study of clinical samples

Once the clinical sample has been received in the microbiology laboratory, it is processed for direct microscopic study and later for culture. The main objective of direct microscopic study is to quickly and efficiently detect the presence of fungi in clinical samples (Arango Arteaga and Castañeda Del Gordo, 2003; Canteros et al., 2017; Clinical and Laboratory Standards Institute (CLSI), 2012; Sutton, 2015).

The choice of the microscopic preparation depends on the type of sample and the suspected fungus; therefore, the diagnostic impression provided by the doctor in the examination request is very important and will initially guide the choice of the preparation. Direct microscopic examination can be performed by means of wet mounts, and microbiological and histopathological stains. Most of the fungi can be observed in the microbiology laboratory with the first two preparations, since they are for routine use, while histopathological stains are not for routine use and are performed in the histopathology laboratory (Arango Arteaga and Castañeda Del Gordo, 2003; Canteros et al., 2017; Clinical and Laboratory Standards Institute (CLSI), 2012). Table 1 shows the advantages and disadvantages of direct microscopic study of clinical samples for mycological diagnosis.

Table 1 Advantages and disadvantages of direct microscopic study of clinical samples for mycological diagnosis.

Advantages	Disadvantages
It is the fastest, most useful and most cost-effective method for the detection of fungal elements, especially for the diagnosis of Invasive Fungal Disease (IFD). Most fungi can be seen with routine preparations and stains used in the microbiology laboratory.	It depends on the experience of the laboratory professional, who has to be well trained in the observation of fungal elements. Its diagnostic sensitivity is low (10^3 – 10^5 fungal elements per mL) and depends on the sample, the patient, and the type of microscopic preparation chosen, in addition to the experience of the laboratory professional.
In many cases, it may be the only evidence of fungal infection when the culture is negative or the clinical sample sent to the laboratory is scarce.	A negative result never rules out the presence of a fungal infection
It is a fundamental method to guide antifungal treatment while the growth of the fungus develops in the culture.	Elements such as cell debris, fat droplets, myelin, leukocytes, fungal mosaic, pollen, tissue fibers, and bubbles can cause confusion and be identified as fungal elements.
Its negativity helps in the interpretation of contaminating fungi isolates in cultures.	It is recommended to carry out various types of preparations (wet mounts and staining) to increase the sensitivity of fungal detection.
Guides the selection of culture media to promote the recovery of the fungus.	It lacks specificity. In most cases the fungus cannot be identified.
As part of the conventional diagnosis, it is the only method that allows diagnosing mycoses produced by non-cultivable fungi such as <i>Pneumocystis jirovecii</i> .	
Can detect the presence of non-viable fungal structures in clinical samples from patients receiving antifungal treatment.

(2007) *Guía práctica. Identificación y diagnóstico en micología clínica*. 2nd edn. Bilbao: Revista Iberoamericana de Micología, pp 3–1–3–22.

Wet mounts

Wet mounts, also known as direct examinations, are one of the main tools used in the routine microbiology laboratory, since they are capable of providing a presumptive diagnosis and allow early therapeutic behavior if fungal elements are observed, such as for example, septate or aseptate hyphae compatible with opportunistic fungi, or characteristic structures of dimorphic fungi (Canteros et al., 2017; Cuenca-Estrella, 2012).

Some samples can be observed directly at low or medium magnification with physiological saline solution or with a Lugol's solution, which provides some coloration to pale fungal structures, but in general, other more effective mounting media are used that favor their observation (Arenas, 2014; Bonifaz, 2012).

Potassium hydroxide (KOH)

It is the most widely used universal mounting medium in the routine microbiology laboratory for wet mounts of clinical samples. It is used primarily to examine opaque and viscous samples such as sputum, exudates, and abscess material, as well as for skin flakes, nails, and hairs. All these samples have in common that they need to be clarified, digested and/or softened before being viewed under the microscope to favor the observation of the fungus morphology and pigmentation. KOH digests the protein and purulent material, and also dissolves the intercellular cement that holds the cells together, which allows to observe the fungal structures that are present in the keratinized tissue (Arango Arteaga and Castañeda Del Gordo, 2003; Arenas, 2014; Bonifaz, 2012; Canteros et al., 2017; Lindsley et al., 2015; Quindós, 2015; Sutton, 2015).

KOH can be prepared at concentrations between 10% and 30% with dyes such as methylene blue, Evans blue and Quink® blue-black ink or Super Quink® permanent blue (both available from Parker), which improve the visualization of fungal structures. The use of the trademark of the two dyes mentioned above is recommended, since inks of other colors or brands are degraded by KOH (Arango Arteaga and Castañeda Del Gordo, 2003; Lindsley et al., 2015). For viscous and opaque samples, as well as those containing a high amount of keratin such as skin flakes, nails, hairs and even corneal scrapings, it is recommended to use a 10% KOH solution. This concentration can be increased to 20% or 30% in the case of samples that also have high fibrin content, such as meliceric crusts and material from warty lesions; they are also often used to digest portions of very thick nails (Arango Arteaga and Castañeda Del Gordo, 2003; Arenas, 2014; Bonifaz, 2012).

The procedure consists of placing one or two drops of KOH (10–30%) with or without additional dyes on a clean microscope slide, adding a drop of the sample in the case of liquid samples, and small fragments in the case of solid samples, add a drop of 10% glycerin, mix gently and cover with a coverslip. The slide is then gently heated to the lighter flame several times, without boiling, to accelerate the action of the KOH on the sample. Subsequently, the preparation is left to rest for 20 min in a humid chamber and is examined under a microscope at low and medium magnification (200× and 400×, respectively). The addition of 10% glycerin and the maintenance of the preparation in a humid chamber allows its observation to be repeated up to 72 h (Arango Arteaga and Castañeda Del Gordo, 2003; Bonifaz, 2012; Canteros et al., 2017; Lindsley et al., 2015).

It is important to consider that the clinical sample, when reacting with KOH, usually generates artifacts that can be confused with fungal structures. On the other hand, KOH, especially at concentrations of 20% and 30%, is more corrosive and over time digests the sample, deteriorating it, which makes it difficult to observe. Heating the slide to a flame accelerates the degradation of keratin, fibrin, mucin and fats saponification, but it also generates the formation of needle shape potassium crystals, which makes the sample difficult to observe; hence the importance of adding 10% glycerin, which minimizes this effect by avoiding evaporation and dehydration (Arango Arteaga and Castañeda Del Gordo, 2003; Bonifaz, 2012; Canteros et al., 2017). It is important to note that KOH is very corrosive, so it is recommended to protect hands from its contact, as well as the microscope stage (Arango Arteaga and Castañeda Del Gordo, 2003).

It is a very efficient technique for the detection of budding blastoconidia, with or without pseudomycelia or true mycelium, septate hyaline (Fig. 1) and dematiaceous mycelial fungi, aseptate mycelial fungi and characteristic structures of endemic dimorphic fungi such as those of the *Paracoccidioides* species complex, *Coccidioides* species complex, and *Blastomyces dermatitidis*, with the exception of *Histoplasma capsulatum* var. *capsulatum* and *Penicillium marneffeii*, whose structures are very small (2–4 µm) and cannot be observed with this mount or with low and medium magnification, since they require microbiological staining and observation at high magnification (1000×) (Arango Arteaga and Castañeda Del Gordo, 2003; Bonifaz, 2012; Canteros et al., 2017).

The experience of the laboratory personnel is essential; both for the preparation of clinical samples and for their subsequent observation and interpretation, since the use of the fresh KOH examination does not ensure that it can effectively differentiate colonization from infection, except in endemic mycosis caused by dimorphic fungi (with the exceptions mentioned above), where the observation of compatible fungal structures is sufficient to initiate a targeted antifungal treatment (Bonifaz, 2012; Canteros et al., 2017).

Other substances similar in action to KOH, which are used for direct examinations are dimethylsulfoxide (DMS) at various concentrations (10–50%), sodium hydroxide (NaOH) at 10–20%, lactic acid at 10–50% and Black Chlorazol E (Arenas, 2014; Bonifaz, 2012; Lindsley et al., 2015).

Black Chlorazol E

It is a commercial dye that uses Chlorazol E (Sigma®) and 10% DMS plus 7% KOH as lighteners, which improves the observation of fungal structures, because it binds especially to chitin, and stains them light green or dark-green, making it a useful reagent for unexperienced or training professionals. The slides should be viewed the same day, since the dye dehydrates over time, and precipitates and degrades with light (Arango Arteaga and Castañeda Del Gordo, 2003; Bonifaz, 2012).

Chinese ink and nigrosine

They are colloidal suspensions of carbon particles that are used to specifically detect in clinical samples the presence of the *Cryptococcus neoformans* and *C. gattii* species complexes, by observing their polysaccharide capsule, which is visualized as a clear and sharp halo that surrounds a blastoconidia with or without buds, on a black background, since the capsule prevents the penetration of the suspension. They are not stains; they are used as contrast methods. The clinical sample par excellence is cerebrospinal fluid (CSF), however, the use of this suspension is also useful in other sample where the presence of this fungus is suspected: sputum, bronchoalveolar lavage (BAL), urine, biopsies, secretions, purulent material and other body fluids (Arango Arteaga and Castañeda Del Gordo, 2003; Canteros et al., 2017; Lindsley et al., 2015; Sutton, 2015).

They have a high sensitivity for the detection of these encapsulated yeasts, since their observation guides the start of antifungal treatment, but it is essential that the laboratory personnel has experience in their observation, since the presence in the sample of red blood cells and leukocytes, as well as artifacts that can be generated during sample process such as air bubbles, talc particles and fat droplets, can cause confusion, leading to the report of a false positive, especially when the yeasts capsule are small (Arango Arteaga and Castañeda Del Gordo, 2003; Canteros et al., 2017; Lindsley et al., 2015).

The procedure consists of placing a drop of the India ink suspension (Pelikan® recommended) or water-soluble nigrosin for microscopy (Merck®) on a clean microscope slide, adding a drop or a small portion of the clinical sample, mixing gently and covering with a coverslip sheet. The amount of suspension to be used affects the sensitivity of the preparation and increases the risk of artifacts, so it must be ensured that it is not excessive or insufficient. The visualization is performed at low (200 ×) and medium magnification (400 ×) immediately after making the preparation, since it dehydrates quickly, making it difficult to observe (Arango Arteaga and Castañeda Del Gordo, 2003; Canteros et al., 2017; Lindsley et al., 2015).

Microbiological stains

These stains are very useful in the routine microbiology laboratory, since they can provide a presumptive diagnosis if yeast or mycelial structures are observed in the sample; provide a definitive diagnosis if very characteristic structures of some fungi are observed; allows to diagnose non-culture fungi when other tools or resources are not available, and the host cellular response generated by the fungus can also be observed (Arango Arteaga and Castañeda Del Gordo, 2003; Ayats et al., 2011; Canteros et al., 2017).

To perform these stains, a small portion of the clinical sample is placed on a clean microscope slide and spread thinly, or an apposition smear is made in the case of biopsies. Then it is left to dry and the chosen stain is carried out. The procedures are in widespread use in microbiology laboratories. To increase the sensitivity and specificity of the diagnosis, it is recommended to make several preparations with various stains.

Gram stain

It is the most used stain in the microbiology laboratory, characterized by being quick and easy to perform. Although yeasts and mycelial fungi are usually Gram positive, some fungi do not take the dyes well with this stain, such as *Histoplasma capsulatum* var. *capsulatum*, *Blastomyces dermatitidis* and both *Paracoccidioides* and *Coccidioides* species complexes. This stain has low sensitivity and specificity, but it will always be useful in the hands of a well-trained and experienced laboratory personnel (Fig. 2) (Arango Arteaga and Castañeda Del Gordo, 2003; Canteros et al., 2017; Pontón and Del Palacio, 2007; Quindós, 2015; Sutton, 2015).

It is advisable to make a first observation of the preparation at medium magnification ($400\times$) in order to locate the presence of fungal structures, and a second one at higher magnification ($1000\times$) to observe particular characteristics. Some hyaline mycelial fungi such as *Aspergillus* spp., *Fusarium* spp. and the *Scedosporium* species complex have similar morphological aspects and stain irregularly, therefore the diagnosis of an infection caused by any of these fungi is presumptive and must be confirmed by culture. In addition, another important aspect related to low specificity, is that it does not allow to differentiate colonization from infection (Arango Arteaga and Castañeda Del Gordo, 2003; Canteros et al., 2017; Pontón and Del Palacio, 2007).

Giemsa and wright stains

They are the stains of preferential use in the microbiology laboratory for mycological diagnosis. Most fungi turn blue-violet or purple (Fig. 3) (Larone, 2011; Lindsley et al., 2015; Sutton, 2015). The Giemsa stain and its modification the Diff-Quick, as well as the Wright stain are effective in the diagnosis of folliculitis caused by the *Malassezia* species complex, in the detection of the intracellular yeast phase of *Histoplasma capsulatum* var. *capsulatum*, from yeasts of the *Sporothrix* species complex, and from trophozoites (ascospores) of *Pneumocystis jirovecii*. Like the Gram stain, they have low sensitivity, and the specificity is subject to the experience of the laboratory personnel (Arango Arteaga and Castañeda Del Gordo, 2003; Canteros et al., 2017; Lindsley et al., 2015).

These stains detect the presence of blastoconidia with and without buds, pseudomycelium or true mycelium, septate and aseptate mycelium, but like the Gram stain, they are not highly recommended for detecting fungal structures compatible with the *Coccidioides* species complex and *Blastomyces dermatitidis*, because they are not stained properly (Canteros et al., 2017).

Giemsa stain also allows differential diagnosis with intracellular parasites such as *Leishmania* spp., but, once again, the experience of the personnel in charge of the diagnosis is vital to differentiate the kinetoplast from the characteristic amastigote forms of this parasite from the intracellular yeasts of *Histoplasma capsulatum* var. *capsulatum*, and even intracytoplasmic granulations of phagocytic cells, which can cause confusion and lead to the report of a false positive (Canteros et al., 2017).

Ziehl-Neelsen staining

This stain is useful to visualize the presence of actinomycetes that are partially acid-fast, such as *Nocardia* spp. (pink), involved in cases of nocardiosis or actinomycetoma (Fig. 4) to differentiate them from other aerobic actinomycetes (Larone, 2011). It is also useful for cases of nontuberculous mycobacteriosis and to rule out or verify co-infection by *Mycobacterium tuberculosis*, particularly in respiratory samples. The Kinyoun stain can be used, which is a modification of the Ziehl-Neelsen (Arango Arteaga and Castañeda Del Gordo, 2003; Bonifaz, 2012; Larone, 2011).

Fig. 4 Ziehl-Neelsen of *Nocardia* spp. from an actinomycetoma (1000×). Photo by María Mercedes Panizo.

Toluidine blue O stain

It is a very useful stain for the detection of *Pneumocystis jirovecii* cysts (ascus) in respiratory samples such as lung biopsies and BAL. The glacial sulfuric and acetic acids present in the reagent remove all the viscous material from the samples, facilitating the visualization of the cysts, which are colored reddish blue or purple, with a slightly blue contrast background. The reagent does not color the trophozoites (ascospores) and has the disadvantage that it must be prepared and used in an extraction chamber and with great caution, due to the acids that compose it (Arango Arteaga and Castañeda Del Gordo, 2003; Lindsley et al., 2015).

Calcofluor white

Calcofluor white is a bleaching agent, widely used in the textile and papermaking industries, that naturally binds to cellulose and chitin. On coming into contact with clinical samples, it clarifies cell debris and coloring fungal structures bright green, with to the use of a fluorescence microscope. It is a very sensitive and simple stain, capable of demonstrating the presence of hyphae, pseudohyphae and yeasts in clinical samples, and particularly useful for the detection of *Pneumocystis jirovecii* structures, which is a non-culturable fungus, but does not allow the visualization of endospores of the *Coccidioides* species complex (Arenas, 2014; Bonifaz, 2012; Lindsley et al., 2015; Sutton, 2015; Zaitz et al., 2010).

The reagent is composed by the union of two solutions: (1) 10 g of KOH in 90 mL of distilled water plus 10 mL of glycerol; (2) 0.1 g of calcofluor in 100 mL of distilled water. This final solution can in turn be diluted 1:10 with 0.05% Evans blue aqueous solution, which will act as a contrast dye. Unfortunately, the disadvantage is that the dye is expensive and that not all routine microbiology laboratories have a fluorescence microscope with 390–420 nm wavelength filters to make observations (Arenas, 2014; Bonifaz, 2012; Zaitz et al., 2010).

Table 2 presents the techniques to perform direct microscopic study according to the clinical samples and Table 3 presents a summary of characteristic features of fungal structures observed in direct examinations of clinical samples.

Histopathological stains

These stains are generally available in specialized laboratories in histopathological diagnosis, so they are not routine stains in the microbiology laboratory. They allow confirming the presence of an invasive mycosis both *ante-mortem* and *post-mortem*.

The tissue obtained by biopsy or cytology is fixed with 10% formalin, it is subsequently included in paraffin, and cuts are made with a microtome, which depending on the tissue will be 3–8 μm thick, which are placed on a clean microscope slide to carry out the stains. The material obtained must be representative of the infectious process in order to provide adequate diagnostic performance. Another important aspect is that the laboratory personnel must be familiar and well trained in the recognition of fungal morphology in tissue and the cellular response that it induces (Bennett, 2015; Canteros et al., 2017; Guarner and Brandt, 2001; Mayayo-Artal, 2004; Quindós, 2015).

The sensitivity and specificity of these stains is given by the possibility of recognizing characteristic fungal morphological structures that can diagnose an invasive mycosis, as well as observing the tissue response of the host, which groups together a wide variety of reactions conditioned by the immune response. Furthermore, fungal structures do not always exhibit their most specific morphological characteristics in the tissue, necessary for their identification, and their observation is generally possible when their presence is abundant, which frequently occurs in the most advanced stages of the disease, when tissue damage it is very important and practically irreversible (Guarner and Brandt, 2001; Mayayo-Artal, 2004; Quindós, 2015). An experienced professional will first perform an observation of the slide at low and medium magnification ($200\times$ and $400\times$), to observe the tissue response, and later will review it using higher magnification ($1000\times$), to search for fungal structures.

Table 3 Summary of characteristic features of fungal structures observed in direct examinations of clinical samples.

Morphology found in the samples	Fungus	Size (μm)	Characteristic features	Laboratory report
Blastoconidia (yeasts with and without budding)	<i>Histoplasma capsulatum</i> var. <i>capsulatum</i>	2–4	Small yeasts, oval to rounded, solitary, with one or more buddings. Often intracellular, located inside macrophages and monocytes, difficult to detect if are scarce. They remain in clusters when are extracellular. They are only observed in stains and with $1000\times$ magnification. When staining, the retraction of the cell membrane simulates the appearance of a capsule, a phenomenon that is not observed with the Gomori-Grocott stain	Intracellular blastoconidia suggestive of <i>Histoplasma capsulatum</i> var. <i>capsulatum</i> With the Gomori-Grocott stain: Small blastoconidia with shape and size compatible with <i>Histoplasma capsulatum</i> var. <i>capsulatum</i>
	<i>Sporothrix schenckii</i> complex	2–6	Small, oval to rounded or cigar-shaped yeasts, with single or multiple budding. They are not common in clinical samples of subcutaneous lesions; they are more frequent in systemic forms. Sometimes it is possible to observe the asteroid body and the Splendore-Hoeppli phenomenon	Blastoconidia suggestive of the <i>Sporothrix schenckii</i> complex. The asteroid body is reported if it is observed
	<i>Cryptococcus</i> species complex	2–20	Oval to rounded yeasts of variable size, with thin dark walls, solitary, with single or multiple budding with a narrow base. It has intracytoplasmic inclusions. The capsule also usually varies in size, thick-walled and refractive, which is sometimes not evident.	Encapsulated blastoconidia suggestive of the <i>Cryptococcus</i> spp. complex.
	<i>Blastomyces dermatitidis</i>	8–15	Oval to rounded yeasts, usually large, thin-walled and birefringent, with single budding attached to the stem cell by a broad base.	Single budding suggestive of <i>Blastomyces dermatitidis</i>
	<i>Paracoccidioides brasiliensis</i> complex	2–60	Oval to rounded yeasts of multiple sizes (anisometric), with intracytoplasmic inclusions. They may be solitary with multiple narrow-based rudder-like buddings or have single budding or short chains of varying size. They have a thick and refractive wall.	Multiple budding blastoconidia suggestive of <i>Paracoccidioides brasiliensis</i> complex
	<i>Lacazia loboi</i>	7–12	Oval to rounded yeasts, characterized by their uniformity in size, very thick-walled and with intracytoplasmic inclusions. They can be found isolated or with multiple budding, and the presence of long yeast chains linked together by an apparent cytoplasmic bridge is usual.	Blastoconidia suggestive of <i>Lacazia loboi</i>
Blastoconidia (yeasts that divide by fission)	<i>Penicillium marneffei</i>	3–4	Oval, intracellular yeasts, located within macrophages and monocytes. They can elongate when they are at the extracellular level. They have a central septum that is formed by fission. They do not give rise to budding. They are only observed in stains and with $1000\times$ magnification.	Intracellular blastoconidia suggestive of <i>Penicillium marneffei</i>
Blastoconidia, pseudohyphae and/or true hyphae	<i>Candida</i> spp.	3–6 (yeast) 5–10 (pseudohyphae)	Yeasts oval to rounded, solitary, with single or multiple buds, often in chains, thin-walled. In pseudohyphae, the blastoconidia remain attached by a depression at the attachment site and are narrow-ended. True hyphae are continuous and septate	Blastoconidia suggestive of <i>Candida</i> spp. Blastoconidia and pseudohyphae suggestive of <i>Candida</i> spp.
Blastoconidia and hyphae	<i>Malassezia</i> spp. complex.	3–8 (yeasts) 2.5–4 (hyphae)	Oval to rounded yeasts, single budding, grouped in compact clusters, thick-walled and refractive. Hyphae are short, thick, and curved, and not always present	Blastoconidia suggestive of the <i>Malassezia</i> species complex. Blastoconidia and hyphae suggestive of the <i>Malassezia</i> species complex.
Aseptate (coenocytic) hyphae	Mucorales	3–25 (average 12)	Large, broad, ribbon-like hyphae often fractured or twisted due to the absence of septa, although they may be occasional. The branches are at right angles (90 degrees)	Hyaline, broad, aseptate (coenocytic) hyphae, suggestive of mucorales
Septate hyaline hyphae	Dermatophytes	3–10	In skin and nails: septate hyaline hyphae of variable diameter and thickness. Intercalary or terminal chains of arthroconidia and chlamydoconidia associated with hyphae, solitary or in clusters, may occur. In hairs: arthroconidia on the periphery of the hair that form a sheath that covers it, indicating ectothrix infection. Arthroconidia formed by fragmentation of hyphae within the hair indicate endothrix infection. Long hyphae forming channels within the hair indicate a favic infection.	Skin and nails: thin, septate, branched and arthrospored hyaline hyphae Hair: Endothrix-like invasion and ectothrix-like invasion.
	<i>Aspergillus</i> spp.	3–12	Hyaline septate hyphae, thick-walled, with dichotomous branching at an angle of 45 degrees, with a tendency to grow in a radial pattern.	Dichotomous septate hyaline hyphae at 45 degrees angle suggestive of <i>Aspergillus</i> spp.
	<i>Scedosporium</i> / <i>Pseudallescheria</i> complex	3–12	It is impossible to differentiate hyphae from those of <i>Aspergillus</i> spp. and other hyaline fungi	Hyaline septate hyphae
	<i>Fusarium</i> spp.	3–12	Hyphae are similar to those of <i>Aspergillus</i> spp., <i>Scedosporium</i> / <i>Pseudallescheria</i> complex and other hyaline mycelial fungi. Both chlamydoconidia and irregular hyphae are common.	Hyaline septate hyphae with chlamydoconidias suggestive of <i>Fusarium</i> spp.

(Continued)

Table 3 (Continued)

<i>Morphology found in the samples</i>	<i>Fungus</i>	<i>Size (μm)</i>	<i>Characteristic features</i>	<i>Laboratory report</i>
Hyaline septate hyphae and arthroconidia (Hyalohyphomycosis)	<i>Geotrichum</i> spp. <i>Trichosporon</i> spp.	2–8 2–8	Rectangular hyphae and arthroconidia with rounded ends Rectangular hyphae and arthroconidia with rounded ends, with solitary and single budding blastoconidia plus pseudohyphae	Hyphae, arthroconidia, blastoconidia and pseudohyphae suggestive of <i>Trichosporon</i> spp.
Dematiaceous septate hyphae (Pheohifomycosis)	<i>Bipolaris</i> spp. <i>Curvularia</i> spp. <i>Exserohilum</i> spp. <i>Exophiala</i> spp. <i>Phialophora</i> spp. <i>Wangiella dermatitidis</i> <i>Xilohypha bantiana</i>	2–6	Polymorphic dematiaceous hyphae. Budding blastoconidia with isolated septa and conidia in chains	
Tinea nigra	<i>Phaeoannelomyces werneckii</i>	1.5–5	Usually large number of branched, thick-walled hyphae and oval blastoconidia, with a single bud and some with a septum. Well defined annelids.	
Spherules	<i>Coccidioides</i> species complex.	10–200 (spherules) 2–5 (endospores)	Spherules of variable size and stages of development, thick-walled and oval to rounded, some with endospores and others empty.	
Eumycetoma granules	<i>Curvularia</i> spp. <i>Exophiala</i> spp. <i>Leptosphaeria</i> spp. <i>Madurella</i> spp. <i>Pyrenochaeta romeroi</i> <i>Acremonium</i> spp. <i>Aspergillus</i> spp. <i>Fusarium</i> spp. <i>Pseudallescheria boydii</i>	65–1000 or greater	Intertwined septate hyphae forming a mass or sclerot of variable shape. The hyphae can be hyaline or dematiaceous, sometimes associated by cementum	Granules (sclerots) suggestive of eumycetoma
Actinomycetoma granules	<i>Nocardia</i> spp.	25–500	Slender, irregular, branched bacilli approximately 1 μm in diameter, intertwining to form soft masses of variable color and shape	Granules suggestive of actinomycetes
Sclerotic cells	<i>Fonsecae pedrosoi</i> <i>ladophialophora carrionii</i> <i>Phialophora verrucosa</i> <i>Rhinocladiella aquaspersa</i>	4–12	Rounded, dematiaceous, thick-walled cells that divide into several planes and form clusters. On some occasions, separate thick-walled dematiaceous hyphae may be found	Sclerotic cells
Black Piedra nodule	<i>Piedraia hortae</i>	Variable	Dematiaceous, multilobed ascocarpus, containing asci with transparent banana-shaped ascospores	<i>Piedraia hortae</i> (Black Piedra) nodule on hair
White Piedra nodule	<i>Trichosporon</i> spp.	Variable	Compact mass formed by hyaline hyphae that break into rectangular arthroconidia. Blastoconidia are difficult to differentiate from arthroconidia	Nodules of <i>Trichosporon</i> spp. (White Piedra) in the hair
Cysts (asci) and trophozoites (ascospores)	<i>Pneumocystis jirovecii</i>	5–12 (cysts—asci) 1–5 (trophozoites—ascospores)	The morphology varies depending on the stain. Gomori-Grocott, toluidine blue O and calcofluor: useful for identifying cysts (asci) as they color their wall. They are rounded or cup-shaped. Trophozoites do not color Giemsa and Wright: useful for identifying trophozoites (ascospores), which are small, with blue cytoplasm and purple nuclei. The cysts do not stain.	Depending on the stain: Trophozoites (ascospores)/cystic forms (asci) suggestive of <i>Pneumocystis jirovecii</i>

Based on data from: Arango Arteaga M and Castañeda Del Gordo E (2003) *Micosis humanas. Procedimientos diagnósticos. Exámenes directos*. Colombia: Corporación para Investigaciones Biológicas (CIB)—Instituto Nacional de Salud (INS). pp. 172–176.; Tille PM (2017) *Bailey & Scott's Diagnostic Microbiology*, 14th edn, pp. 768–770, Missouri: Elsevier.; Ashbee HR (2015) General approaches for direct detection and identification of fungi. In: Jorgensen JH and Pfaller MA (eds). *Manual of Clinical Microbiology*, 11th edn, pp. 1966–1968, Washington, DC: ASM Press.

From the didactic point of view, the groups of tissue reactions induced by pathogenic fungi are presented below, based on the model described by Baker (1947) and Zaitz et al. (2010).

- a) Group I: chronic inflammatory process, with the presence of suppuration, macrophages, giant cells, caseous necrosis and fibrosis. This group includes the majority of deep and subcutaneous mycoses: North American Blastomycosis, Paracoccidioidomycosis, Coccidioidomycosis, Sporotrichosis and Lacaziosis or Jorge Lobo's disease.
- b) Group II: predominance of suppuration, combined with an inflammatory infiltrate at the expense of macrophages, giant cells and fibrosis, without caseous necrosis. This group is represented by mycetomas (actinomycotic and eumycotic) and chromomycosis.
- c) Group III: suppuration generally absent, without macrophages, giant cells, necrosis or fibrosis. This group includes Histoplasmosis, whose etiological agent is intracellular, and Cryptococcosis, which occur in immunocompromised individuals.
- d) Group IV: acute inflammation and necrosis. This group includes fungal diseases with tissue necrosis and an acute exudative inflammatory response, in which fungal structures are found. The fungi that cause these diseases have a similar morphological presentation in the tissue; therefore, they must be confirmed by biopsy culture. The diseases are Aspergillosis, Mucormycosis, Hyalohyphomycosis and Pheohifomycosis, the latter two caused by a wide variety of different genera.
- e) Group V: absence of inflammatory reaction. This group includes superficial candidiasis and superficial mycoses, where the fungus is confined to the corneum stratum of the skin or to keratinized structures, respectively.

Hematoxylin-Eosin (H&E) stain

It is a very versatile and useful stain for the histopathological diagnosis of fungal diseases, particularly invasive diseases and eumycotic mycetomas, since it allows to show both the presence of the fungus (hyaline or dematiaceous), as well as the tissue response of the host against it. Fungal structures such as blastoconidia and pseudohyphae of *Candida* spp., as well as the hyphae of *Aspergillus* spp. and of the mucorales are well stained, while other fungi are partially stained or not stained. However, in the latter case, it is possible to appreciate the contour of the non-colored elements and thus show the presence of the fungus. Therefore, the professional's experience is essential (Arango Arteaga and Castañeda Del Gordo, 2003; Bennett, 2015).

Due to the fact that some fungi have similar morphologies in the tissues, the differentiation and interpretation of the stain is usually difficult, generating confusion and possible reports of erroneous results (Canteros et al., 2017). The hyphae of hyaline mycelial fungi are usually colored purple (eosinophils) and those of dematiaceous fungi retain their pigment and can be seen as brown. Yeasts tend to be colored blue or purple (basophilic), although some may not take the stain efficiently. In all cases, careful and expert observation is necessary in order to establish a presumptive diagnosis (Arango Arteaga and Castañeda Del Gordo, 2003; Larone, 2011).

Gomori-Grocott methenamine silver stain

It is one of the most used stains to confirm the presence of fungal structures in tissues, being the stain of choice for the diagnosis of invasive fungal diseases (IFD) (Arango Arteaga and Castañeda Del Gordo, 2003; Bennett, 2015; Bonifaz, 2012; Canteros et al., 2017; Lindsley et al., 2015). The fungal structures are well outlined in brown to black color, due to the deposit of reduced silver in the places where the aldehydes are located, a product of the oxidation of the hydroxyl groups of the fungal cell wall polysaccharides in the presence of the chromic acid. The contrast dye is Malachite green, which provides a green background that highlights the dark color of the fungal structures (Arango Arteaga and Castañeda Del Gordo, 2003).

This stain is considered of choice for the diagnosis of Pneumocystosis in BAL samples, being also very useful for diagnosing Paracoccidioidomycosis and Mucormycosis, however, it has limitations in the case of intracellular fungi, since it is not possible to observe the tissue reaction of the host, and it tends to color the fungi densely, making it difficult to observe structural details (Bonifaz, 2012; Larone, 2011).

Periodic acid schiff stain (PAS)

Like the Gomori-Grocott stain, it is considered a routine stain for the identification of fungal structures in tissues, since many of the fungal structures have basophilic and eosinophilic characteristics that allow their visualization clearly and sharply, much better than with H&E stain (Bonifaz, 2012; Lindsley et al., 2015). The stain is based on the property of the fungal wall neutral mucopolysaccharides to oxidize in the presence of periodic acid to form aldehydes, which fix the fuchsin of the Schiff's reagent and color from dark pink to magenta with variable intensities (Arango Arteaga and Castañeda Del Gordo, 2003; Lindsley et al., 2015).

With this stain, intracellular fungal structures can be observed, such as yeasts in the case of Histoplasmosis and spherules with endospores in cases of Coccidioidomycosis. It is also useful in cases of actinomycotic mycetoma and botryomycosis (Bonifaz, 2012) and to demonstrate the refractive double-contour wall of *Blastomyces dermatitidis*, which is not visible with the Gomori-Grocott stain (Larone, 2011).

Mayer's Mucicarmine stain

This stain is ideal for the identification of the mucopolysaccharide capsule of *Cryptococcus neoformans* and *C. gattii* species complexes, since the process of tissue fixation and paraffin removal shrinks the capsule around the cryptococcal cell, providing an intense red to pink border, but the wall itself is not stained. This also happens in clinical samples such as CSF and other biological fluids (Arango Arteaga and Castañeda Del Gordo, 2003; Bennett, 2015; Bonifaz, 2012). It also colors the cell walls of *Blastomyces dermatitidis* and *Rhinosporidium seeberi*, the latter a parasite frequently studied in medical mycology (Larone, 2011).

Fontana-Masson stain

This stain is very useful for the presumptive diagnosis of mycoses caused by dematiaceous fungi, such as Pheohifomycosis and black grain eumycetomas, and the *Cryptococcus neoformans* and *C. gattii* species complexes, since it highlights the melanin they contain in their walls (Bennett, 2015; Bonifaz, 2012; Larone, 2011; Lindsley et al., 2015). Melanin has polyphenolic bodies that, when combined with the silver salts in the reagent, are reduced to their metallic state, allowing it to be observed in black (Arango Arteaga and Castañeda Del Gordo, 2003).

Cultures

The collection and transport to the microbiology laboratory of a clinical sample in optimal conditions, the pretreatment of the sample if necessary, as well as the choice of culture media, temperature and incubation time are the factors that influence the recovery of pathogenic fungi. Currently, there is a wide variety of culture media for primary isolation and it is important to note that no single culture medium is sufficient for the recovery and growth of all medically important fungi; therefore, it is necessary to use a suitable battery. On the other hand, their choice in the laboratory basically depends on the preferences and experience of the professional in charge of the diagnosis (Lindsley et al., 2015; McGowan, 2015; Sutton, 2015; Tille, 2017).

In order to select a suitable battery of culture media, the following factors need to be considered:

- a) The choice of culture media depends on the sample type to be processed (Clinical and Laboratory Standards Institute (CLSI), 2012; Ellis et al., 2007). In the case of non-sterile samples, which may contain associated bacterial flora, it is necessary to choose a culture media battery that includes media with antibiotics that inhibit bacterial growth but allow the fungus growth, and another medium with or without antibiotics that also contains cycloheximide, to inhibit contaminating fungi or saprophytes. The battery for sterile samples should include one or two non-antibiotic media plus one medium with antibiotics (Clinical and Laboratory Standards Institute (CLSI), 2012; Ellis et al., 2007; Lindsley et al., 2015; McGowan, 2015; Sutton, 2015; Tille, 2017).
- b) Sabouraud Dextrose Agar (SDA) without antibiotics is the traditional medium for the primary isolation of fungi (Scognamiglio et al., 2010). Chloramphenicol alone or with other antibiotics such as gentamicin is included in some primary culture media to inhibit bacterial growth. However, if the clinical suspicion is *Nocardia* spp. and other aerobic actinomycetes, only SDA should be used (Clinical and Laboratory Standards Institute (CLSI), 2012; Lindsley et al., 2015; Scognamiglio et al., 2010; Sutton, 2015; Tille, 2017).
- c) Endemic dimorphic fungi grow best in enriched culture media such as heart-brain with antibiotics and enriched with 5–10% lamb blood. The latter has the disadvantage that inhibits sporulation, therefore, these fungi must be subcultured immediately to enriched blood-free media to promote conidia formation and perform molecular tests (Clinical and Laboratory Standards Institute (CLSI), 2012; Lindsley et al., 2015; Sutton, 2015; Tille, 2017).
- d) When it is required to detect the growth of a specific pathogen, the culture media battery can vary. In the case of *Candida* spp. a chromogenic medium can be used, which is both selective and differential (Murray et al., 2005). In the case of dermatophytes, Mycosel™ can be included. For *Malassezia* spp. SDA must be supplemented with sterile olive oil, adding 0.5 mL on the surface of the plate after seeding the sample; Dixon and Leeming media can also be used if available in the laboratory (Clinical and Laboratory Standards Institute (CLSI), 2012; Lindsley et al., 2015).
- e) The use of culture media dispensed in plates or tubes is frequently a matter of discussion, since it is necessary to consider the biosafety measures related to the seeding of clinical samples and the subsequent growth of the fungi, especially if it is endemic. The plates provide more surface area for the samples seeding and better contact with the air, which favors the fungus growth, the recovery of the colonies and the preparation of wet mounts, however, the culture medium tends to dehydrate and get contaminated faster. In these cases, it is recommended to seal the plates individually or place them in a bag with permeable gas, which avoids environmental contamination and increases safety when working with cultures, an activity that should always be carried out using a biological safety cabinet. The use of agar slants in tubes reduces contamination and increases safety, but decreases the growth surface for the fungus and makes it difficult to access the colonies due to the narrow mouth of the tube (Clinical and Laboratory Standards Institute (CLSI), 2012; Lindsley et al., 2015; Sutton, 2015; Tille, 2017). A low-cost and accessible alternative for laboratories is the use of Parafilm® laboratory film to seal the plates individually. The use of the culture media is ultimately at the discretion of the laboratory personnel.
- f) The culture media already seeded must be incubated aerobically at room temperature or in an incubator between 25 °C and 30 °C. The incubation time depends on the presumptive clinical diagnosis and the culture type requested. For example, for *Candida* spp. incubation does not exceed 72 h; cultures for dermatophytes are incubated for 7–15 days, while cultures for endemic fungi are routinely incubated for up to 4 weeks (Clinical and Laboratory Standards Institute (CLSI), 2012; Lindsley et al., 2015; Sutton, 2015; Tille, 2017). For the other pathogenic fungi, an incubation time of up to 3 weeks is sufficient (Labarca et al., 1998; Sutton, 2015). Cultures should be checked every 2 to 3 days for the first 2 weeks and then once a week, and should be incubated for 21–30 days before being reported as negative (Lindsley et al., 2015; Sutton, 2015; Tille, 2017).

Considerations for yeast identification

The identification of yeasts by conventional methods can be carried out according to three criteria: morphological, biochemical-physiological and immunological.

Morphological criteria

Most of the morphological methods are fast and allow the identification of some yeast until genus and species in a time not exceeding 48 h. The most used are the visualization of the macroscopic characteristics in solid culture media, germ tube formation, chlamydoconidia production, the Dalmau method that allows the study of microscopic morphology in Corn Meal Agar (CMA), and the chromogenic culture media (Campbell et al., 2013; Freydière et al., 2001; Howell et al., 2015; Larone, 2011; Linares Sicilia and Solis Cuesta, 2007; Pincus et al., 2007; Zaitz et al., 2010).

- a) *Macroscopic characteristics in solid culture media*: the appearance of the colonies is observed (mucous or shiny, opaque, butyric, smooth, rough, raised or flat, velvety), size and color (Fig. 5).
- b) *Germ tube production*: consists of placing a small portion of a colony obtained from a 24-h culture in 0.5 mL of serum and incubating at 37 °C for 2 h. This test is positive for *Candida albicans*/*Candida dubliniensis*, which produce a thin continuous tube, without constriction at the site of origin. *Candida tropicalis* can also produce a germ tube after incubation in serum for 2 h at 37 °C, but the difference is that the germ tube presents a constriction at the exit point of the yeast and the diameter is greater; the tube is not continuous or thin like that produced by *Candida albicans*/*Candida dubliniensis*.
- c) *Chlamydoconidia production*: to obtain this resistance structure characteristic of *Candida albicans* and *Candida dubliniensis*, it is necessary to use the bile agar medium, placing a small portion of a yeast colony obtained from a 24-h culture in it, and incubating at 28 °C for 24–48 h (Fig. 6).
- d) *Dalmau method*: consists of streaking a portion of the colony in the middle of CMA and placing a coverslide on top of it. Subsequently, incubated at 28 °C for 24–48 h and then the characteristic morphology for each species is observed under the microscope. The characteristic morphology of the five *Candida* spp. most frequently isolated in clinical samples is described below (Fig. 7).
 - Microscopic morphology of *Candida albicans*/*Candida dubliniensis* in CMA: they produce branched pseudohyphae with blastoconidia of regular size, round and budding, with smooth walls, arranged in clusters at the points of constriction of the pseudohypha; the characteristic chlamydoconidia of these species may or may not be present. Chlamydoconidia are round, smooth and thick-walled, with cytoplasmic inclusions; they are generally located in a terminal position in the pseudohypha, although they can also appear interspersed (Fig. 7A).
 - Microscopic morphology of the *Candida parapsilosis* species complex in CMA: they produce branched pseudohyphae with small oval or elongated blastoconidia, with smooth walls, arranged in small clusters along the pseudohypha. The blastoconidia may have buds and the pseudohypha, in most cases, has a curved appearance on one side (Fig. 7B).
 - Microscopic morphology of *Candida tropicalis* in CMA: produces branching pseudohyphae with single round or oval blastoconidia of regular size or in small groups with little budding, smooth walls, widely distributed throughout the pseudohypha. It rarely produces chlamydoconidia and if they occur they are very scarce (Fig. 7C).
 - Microscopic morphology of *Candida glabrata* in CMA: it does not produce pseudohyphae or pseudomycelium. Small, oval blastoconidia with uni or bipolar budding are observed; they are smooth and thin walled (Fig. 7D).

Fig. 5 *Epidermophyton floccosum* on PDA. Photo by María Mercedes Panizo.

Fig. 6 Chlamydoconidia of *Candida albicans* (1000 ×). Photo by María Mercedes Panizo.

- Microscopic morphology of *Candida krusei* in CMA: produces long, slightly thick or robust branched pseudohyphae with elongated or cylindrical blastoconidia of medium size and smooth walls, cluster at regular intervals, arranged as crossed trunks (Fig. 7E).
- e) *Chromogenic culture media*: is based on the detection of enzymatic activities by yeasts through the specific hydrolysis of a chromogenic substrate in the presence of an indicator.
 - With the commercial culture media CHROMagar™ *Candida* (CHROMagar Company, France) and CHROMagar™ (Becton-Dickinson, France), three species of *Candida* can be presumptively identified with high reliability by colony color. *Candida tropicalis* produces smooth, creamy colonies with an intense blue color or dark blue-green colonies, both with a metallic hue; *Candida krusei* produces pale pink, downy or slightly velvety, dull or dry colonies with a flat surface; *Candida albicans* produces emerald green, shiny, smooth, and creamy colonies. The colonies identification of these *Candida* species, as well as the colonies of other colors obtained on these media, must be confirmed by conventional methods (Fig. 8).
 - It is important to remember that *Candida dubliniensis* behaves phenotypically and biochemically the same as *Candida albicans*, and therefore also produces green colonies, making one species indistinguishable from the other, although some authors point out that *Candida dubliniensis* produces dark green colonies and it does not grow at 42 °C. To differentiate them it is necessary to use molecular techniques, not always available in the routine microbiology laboratory.
 - The use of this medium is recommended to obtain primary isolation from clinical samples coming from critically ill patients with clinical suspicion of candidiasis, and thus offer preliminary guidance in confirming the diagnostic impression. This makes it possible to establish an adequate and effective antifungal therapy in the shortest possible time. Another important advantage of chromogenic medium is the detection of two or more *Candida* species that may be present in clinical samples and cannot be detected in common culture media.
 - This culture medium has been widely commercialized, with differences in the detection of the enzymatic activities of *Candida* spp., among which are chromID™ *Candida* (bioMérieux, France), CandiSelect™ 4 (BioRad, United States) and Colorex *Candida*® (Biomedics).

Biochemical-Physiological criteria

Physiological methods can be classified into rapid and conventional tests. Rapid tests include urease production, phenol oxidase production, and growth in 6.5% sodium chloride (NaCl). Tests such as thermotolerance and resistance to cycloheximide are considered complementary. Conventional methods based on biochemical criteria are nutrient assimilation (carbohydrates and nitrogen sources) and carbohydrate fermentation, which are costly, laborious and time-consuming techniques. These methods have been displaced in the laboratory by automated identification systems (Freydière et al., 2001; Howell et al., 2015; Linares Sicilia and Solis Cuesta, 2007; Pincus et al., 2007; Zaitz et al., 2010).

- a) *Urease production*: this test reveals the urease enzyme activity present in some species of yeast. The urea hydrolysis occurs in Christensen's urea agar medium, after inoculating the yeast in the medium for 48 h at 28 °C. A positive test is manifested by the color change from half orange to fuchsia. Among the yeast genera that are urease positive are *Cryptococcus*, *Rhodotorula*, and *Trichosporon*.

(A) *Candida albicans* (emerald green colonies) and *Candida tropicalis* (dark blue-green colonies); (B) *Candida albicans* (emerald green colonies), *Candida krusei* (pink colonies) and beige colonies (other yeasts). Photos by Maria Mercedes Panizo.

- b) *Phenol oxidase production*: *Cryptococcus neoformans* and *C. gattii* produces phenol oxidase, an enzyme necessary for the metabolism of 3,4-dihydroxyphenylalanine (DOPA) and other phenolic compounds in the synthesis of melanin. This is evidenced by the production of a dark brown or black pigment around the *Cryptococcus neoformans*/*C. gattii* colonies in the solid Oxgall-Tween-caffeic acid culture medium.
- c) *Growth test in 6.5% sodium chloride (NaCl)*: allows presumptive differentiation of *Candida albicans* from *Candida dubliniensis*. It consists of preparing a 0.5 McFarland suspension of the suspected yeast and adding 25 µL of this suspension to a test tube with 1 mL of 6.5% NaCl and a drop of 10% yeast extract; subsequently, it is incubated at 37 °C for a maximum of 72 h. If at the end of this time turbidity and growth are obtained in the tube, the identification will correspond to *Candida albicans*. The opposite result, without turbidity and without growth, will presumably correspond to *Candida dubliniensis*. It is important to keep this isolate for later confirmation by molecular biology techniques.
- d) *Thermotolerance test*: this consists of incubating the yeast colonies at a temperature of 42–45 °C. Most non-*Candida albicans* species do not grow at temperatures above 37 °C.
- e) *Resistance to cycloheximide or actidione*: most of the non-*Candida albicans* species are sensitive to actidione and therefore do not grow in this medium; few are resistant to this antibiotic and the most important resistant specie is *Candida albicans*.

- f) *Carbohydrates assimilation (auxanogram)*: it is based on the property that yeasts have of using sugars as a source of carbon under aerobic conditions. The solid basal medium for the auxanogram is free of sugars and alcohols.
- g) *Nitrates assimilation (KNO₃)*: consists of the use of nitrates by yeasts as the only source of nitrogen. A basal medium with glucose is used and urea or KNO₃ should be used as positive controls.
- h) *Carbohydrates fermentation (zymogram)*: it is based on the property that yeasts have of using sugars in anaerobiosis, which is evidenced by the production of gas. The most commonly used sugars are: glucose, maltose, sucrose, galactose, trehalose and lactose in concentration at 2% and raffinose at 4%. The sugars are prepared in basal medium (peptone, yeast extract and water). The formation of gas (CO₂) is detected by incorporating an inverted Durham tube into the liquid medium. The observation is made daily, because the gas can be reabsorbed.
- i. *Automated identification systems*: automated identification systems have had a great impact on the microbiology laboratory, because they considerably improve handling of large volumes of microorganisms for identification, which in turn allows providing an early diagnosis. In the last decades, manual and automated commercial methods have been developed, based on nutrients assimilation. Manual and semi-automated commercial methods include Auxacolor™ (Bio-Rad, United States), Uni-Yeast Tek (Remel, United States), API 20C® AUX and API® ID32C (bioMérieux, France), RapID Yeast Plus System (Innovative Diagnostic System, United States) and Fungiscreen 4H™ (Bio-Rad, United States). Automated commercial methods include Vitek® 2 (bioMérieux, France), Biolog YT MicroPlate™ (Biolog, United States) and Rapid Yeast Identification Panel Micro-Scan® (Dade Behring, United States). They are faster than conventional methods, easy to use and have software for the identification of the different microorganisms.

Conventional yeast identification methods consume a variable time from 2 to 21 days and require the use of identification keys, but a good identification is achieved. Automated methods can identify yeast in 4–72 h, which is a great advantage for laboratory and clinical patient management. But these methods have not been able to completely replace the conventional ones. Yeast identification, through the use of automated equipment, must be accompanied by additional tests that complement the identification, such as the use of chromogenic culture media and microscopic visualization of yeast in CMA using Dalmau method. In addition, the microbiologist in charge of operating these systems must be constantly updated, especially in aspects related to taxonomy.

Immunological criteria

Immunological methods are based on agglutination with latex particles, using specific monoclonal antibodies (Freydière et al., 2001; Freydière et al., 2003; Howell et al., 2015; Linares Sicilia and Solis Cuesta, 2007; Pemán et al., 2004; Pincus et al., 2007; Zaitz et al., 2013).

- a) Bichro-latex albicans® (Fumouze) is a method for the rapid identification of *Candida albicans* isolates by agglutination of latex particles using a monoclonal antibody specific for *Candida albicans*.
- b) Krusei-color® (Fumouze) is a method for the identification of *Candida krusei* isolates by agglutination of latex particles, using a monoclonal antibody that specifically reacts with the antigen located on its wall.
- c) Bichro-Dubli® (Fumouze) is a method for the rapid identification of *Candida dubliniensis*, based on the coagglutination of blastospores with latex particles coated with monoclonal antibodies, which allows the specific detection of a *Candida dubliniensis* antigen located on the cell surface.

Considerations for filamentous fungi identification

The identification of filamentous fungi is carried out through a combination of tests (Arenas, 2014; Campbell et al., 2013; Larone, 2011):

- a) Morphological characteristics of the colony in culture.
- b) Microscopic morphological characteristics.
 - Hyphae: thickness, ramifications, presence or absence of septa, and color.
 - Asexual spores and conidiogenous cells.
 - Sexual spores and structures where they are formed.
 - Any attached formation (ornamentation).

The morphological characteristics of the colonies have limited value in identifying filamentous fungi, due to the natural variation that exists between isolates and colonies when growing in different culture media. Although the fungi that are most frequently recovered in the laboratory can be easily recognized, colonial morphology is an unreliable criterion that should be used only to complement the microscopic morphological characteristics of the organism.

It is also important to take into account the growth time of the fungus in the culture, however, its value is limited, because the time varies depending on the fungus: slow-growing ones form mature colonies in 11–21 days; those of intermediate growth form mature colonies in 6–10 days, and those of fast growth form mature colonies in 5 days or less.

Colony color can be important. Laboratory personnel should be sure to record both the front and reverse side of the culture. The topography of the colony describes the different elevations and shapes that it can present in cultivation. It can be described as warty, slightly raised in the center, or with radiating furrows from the center, among other descriptions. The texture of the colony must also be taken into account. It can see cottony, velvety, glabrous, granular, powdery, and woolly textures, among others. Incubation conditions and culture media should also be considered.

In most cases, the microscopic morphological characteristics provide presumptive and sometimes definitive identification of the fungus. A major disadvantage is that these structures tend to develop slowly and appear after several days or weeks of incubation. Laboratory personnel must be well trained to recognize the microscopic characteristics of filamentous fungi in their asexual phase, which is the frequently observed one in the laboratory when the fungi are recovered from culture. The development stages of conidia and conidiogenous cells (conidiogenesis) have stable characteristics that are used in the classification of fungi, including their formation mode, the mycelium structure that supports the conidia and their accommodation, which are the basis for species identification. In medical mycology these attributes are of special importance, since the teleomorphic or sexual state is rarely found.

Fungi can be prepared for microscopic observation using various techniques. The following methods can be used:

- a) Analysis of a fragment of the culture (tease mount): consists of taking a fragment of the colony, dilacerate it and observe it with lactophenol blue. This is the usual method, but if not done carefully it can destroy conidiogenous cells and make identification difficult.
- b) Transparent adhesive tape method (Rush-Munro): it is a variant of the prior technique and allows the fungal structures to be observed almost without alteration. A small square of adhesive tape is cut out and adhered to the terminal part of the nichrome needle, and then the adhesive part is applied on the colony and then placed on a slide with a drop of dye. The platinum needle is removed, added another drop of dye, a coverslip is placed and observed under a microscope.
- c) Slide culture or micro-culture: it is the most precise and allows observing the fungal structures in situ. It consists of obtaining a culture on a glass slide and observing the fungus without deterioration of its morphology.
 - Prepare a sterile 90-mm diameter Petri dish and cover the inside bottom with a piece of sterile filter paper.
 - Place a sterile glass rod on the sterile filter paper.
 - Place a clean flamed microscope slide on the glass rod.
 - Cut a block of 1-by-1 cm from a Petri dish of Potato Dextrose Agar (PDA) with a sterile scalpel and place it in the center of the slide.
 - Inoculate the fungus onto the centers of the four sides of the agar block with a nichrome needle.
 - Place a flamed coverslip over the block, and apply slight pressure to ensure adherence.
 - Place approximately 1,5 mL of distilled sterile water on the filter paper, cover the Petri dish with the lid, and incubate at room temperature, preferably in the dark, or in a cabinet at 25 °C.
 - Examine the Petri dish periodically for growth and add water if it is necessary.
 - When growth is visible, remove the coverslip with forceps, take a microscope slide, place a drop of lactophenol blue and then place the coverslip.
 - Remove the agar block from the slide and put it into a container with disinfectant. Put a drop of lactophenol blue on the slide and cover it with a new coverslip.
 - Examine the wet mounts on the microscope, looking for reproductive structures.

The preferred technique for demonstrating diagnostic structures and conidiogenous structures for most filamentous fungi is slide culture. In addition, this method can provide a permanent mount that can be preserved in a slide collection for future study, and is extremely useful for comparison with other similar or atypical isolates.

It is important to recognize that the definitive identification of filamentous fungi frequently requires molecular analysis, to support morphological identification. One of the consequences of these analysis has been the recognition that many clinically important species are actually species complexes, morphologically identical but genetically different. In circumstances when identification based on morphology is not sufficient, the fungus is a candidate for identification by molecular techniques.

This approach is very useful when the fungus presents an atypical or non-specific morphology, do not sporulate properly and requires special culture media. However, in the routine laboratory, for the identification of filamentous fungi, observation of their microscopic morphology continues to be the standard approach, although it has limited diagnostic capacity, since not all laboratories have trained personnel or equipment for performance molecular analysis. Importantly, any filamentous fungus recovered in culture must be examined and handled in a biological safety cabinet.

Diagnosis of fungal diseases by culture-independent microbiological methods

Obtaining the fungus causing a fungal infection, especially from sterile specimens, is still the gold standard for definitive diagnosis, but this process sometimes takes several weeks to provide results, reducing sensitivity. On the other hand, positive cultures from non-sterile samples can be due to both colonization and infection, and distinguishing the two is not always easy. A presumptive diagnosis can also be made using wet mounts, as well as microbiological and histopathological stains; however, obtaining adequate clinical specimens, both for culture and for these mounts is not always possible. Non-culture-based mycological diagnostic methods can provide more timely results and are very useful tools, since the diagnosis of an invasive fungal infection cannot always be made by culture and histopathological studies, but these methods have not yet completely replaced the culture, therefore, should be used as complementary methods and its results should be interpreted individually, taking into account the clinical context of the patient.

Non-culture-based diagnostic methods are classified into five groups. They include the detection of antibodies in the host, fungal antigens, metabolites or structural components, proteins, and nucleic acids by molecular techniques. Only a small group of tests have been shown to be clinically useful, and very few are commercially available.

Antibody detection in the host

The use of antibody detection in serum or other body fluids is important in the diagnosis of endemic mycoses such as Histoplasmosis, Paracoccidioidomycosis, Coccidioidomycosis, and South American Blastomycosis, as well as in two clinical manifestations of aspergillosis, such as allergic bronchopulmonary disease and aspergilloma. However, they are not useful in most opportunistic mycoses, due to their low sensitivity and specificity, particularly in immunosuppressed patients. Among the most important limitations of these techniques are the ability to produce antibodies by the patient, the time of evolution of the disease and the quality of the antigens used (Pfeiffer and Wong, 2015; Quindós, 2015). Additionally, the detection of antibodies does not help to distinguish between an acute or chronic infection, because the ability to produce antibodies is individual in patients, and may be delayed in some cases; finally, it is possible to detect the presence of antibodies against some antigens in people asymptomatic, which reduces the diagnostic specificity of these tests (Pfeiffer and Wong, 2015).

The tests most used today are double radial immunodiffusion (ID) on agarose gel, counter-immunoelectrophoresis (CIE), complement fixation (CF), indirect immunofluorescence (IIF) and enzyme-linked immunosorbent assay (EIA). The latter is rapidly replacing the others due to its greater sensitivity (Pfeiffer and Wong, 2015; Quindós, 2015).

Histoplasmosis

For the detection of antibodies against Histoplasmosis the most used tests are the ID, FC and CIE. In the ID and CF tests, histoplasmin is composed of two species-specific antigens of *Histoplasma capsulatum* which are the H and M antigens. Antibodies against the H antigen are formed during acute Histoplasmosis, while antibodies against the antigen M are formed both during both acute and chronic form of the disease, and are usually the first to appear after seroconversion. Antibodies against the H antigen signify active and progressive infection, although they are only detected in 10–20% of patients with exposure to the fungus, while antibodies against the M antigen are detected between 6 and 8 weeks after exposure to the fungus in 50–80% of patients, persisting for years, even though the patient has recovered from the infection. This indicates that its presence does not help to distinguish between current and past infection (Linder and Kauffman, 2021; Pemán et al., 2017; Pfeiffer and Wong, 2015).

The ID is a widely disseminated test because it is fast, safe, inexpensive and simple to perform, allowing the diagnosis of 85% of the cases of histoplasmosis in immunosuppressed patients. It can be performed using serum, peritoneal fluid, and CSF specimens in cases of meningeal histoplasmosis. This test can be made semi-quantitative, performing serial double dilutions of the specimens to obtain the antibody titer (Linder and Kauffman, 2021; Pemán et al., 2017; Reviákina et al., 2007). The interpretation of the semi-quantitative results of the ID is very important, since the obtained titers can be presumptive or diagnostic of histoplasmosis. Titers between 1:8 and 1:16 have a presumptive value and should be assessed in the clinical context of the patient, while titers equal to or greater than 1:32 are diagnostic for active histoplasmosis. The decrease in titers during treatment is useful to follow the effectiveness of the treatment and the improvement of the patient (Linder and Kauffman, 2021; Reviákina et al., 2007).

Asymptomatic individuals residing in endemic areas often have low antibody titers. Titers decrease as time passes after exposure, but can remain positive for years. False negative results of these tests are possible in immunosuppressed patients and during the early stages of infection. False positives can occur in 15% of patients, due to cross-reactions with paracoccidioidomycosis, blastomycosis, and coccidioidomycosis agents (Pfeiffer and Wong, 2015; Reviákina et al., 2007). In these cases, it is recommended to obtain the titers of all agents, to know which of them is causing the infection (Reviákina et al., 2007). Similar results to ID are obtained with the CIE technique, which is faster and more sensitive, but has the disadvantage of requiring electrophoresis, which increases costs. On the other hand, FC has a similar sensitivity to ID, but its main drawback is that it is very labor intensive.

Paracoccidioidomycosis

For the detection of antibodies against paracoccidioidomycosis, in patients with risk factors and exposure to the fungus but without immunodeficiencies, the ID, CF, CIE, IIF and EIA tests have been used, with similar sensitivities, especially if it is possible to combine the least two of the mentioned techniques (Pfeiffer and Wong, 2015; Wheat, 2009).

The most widely used method is ID and its usefulness for this disease is similar to that of histoplasmosis, since it allows diagnosing 94% of paracoccidioidomycosis in patients without immunosuppression. FC is used in the same way as ID. The values of the interpretation of the titers for the diagnosis of the disease are the same as for histoplasmosis, being the high titers indicative of the severe form of the disease, which can be detected even up to 2 years after the patient recovered from it (Reviákina et al., 2007; Pemán et al., 2017; Pfeiffer and Wong, 2015), although other authors affirm that any positive value obtained, even when the dilutions are low, is indicative of the infection (Guimarães et al., 2006; Pires de Camargo and Fabiano de Franco, 2000).

Coccidioidomycosis

Three tests are currently used, which are useful for diagnosing the disease in non-immunosuppressed patients: ID, CF and EIA. They are simple to perform and have good sensitivity and specificity. IgM antibodies are detected during the first week of infection and IgG appear between the second and third week. The ID test is widely used in endemic areas for the diagnosis and evaluation the prognosis of the disease and its results must be interpreted in conjunction with the patient clinical symptoms (Pemán et al., 2017; Pfeiffer and Wong, 2015). Titers from 1:16 onwards obtained from serum correlate with the severity of the disease (Reviákina et al., 2007). In some patients the antibodies remain for up to 6 months and in rare cases they can remain even after successful treatment. The reappearance of antibodies in a patient with a history of coccidioidomycosis is considered a reactivation of the disease (Pemán et al., 2017; Pfeiffer and Wong, 2015).

The CF test can be performed in serum and body fluids and, like ID, is semi-quantitative and it is recommended to report the titer when it is positive. The use of serial double dilutions in ID and CF help the physician to assess both the progression and cure of the disease (Pemán et al., 2017). EIA are simple and precise tests that can be performed in serum and CSF, however, false positives can occur when obtaining a positive IgM together with a negative IgG, and the validity of the result in asymptomatic patients or without classic symptoms should be questioned (Blair et al., 2013); this finding is relatively common (~10%) and one review has reported false negative rates between 0% and 82% (Nguyen et al., 2013). For this reason, EIA must be confirmed with ID or CF. All of these tests are not useful for diagnosing the disease in immunosuppressed patients (Pfeiffer and Wong, 2015).

Blastomycosis

The tests used for the detection of antibodies against antigen A of *Blastomyces dermatitidis* are ID, FC and EIA, with variable sensitivity and specificity values. When comparing them, the ID test is the most specific, the EIA is the most sensitive, and the FC has low values for both parameters (Linder and Kauffman, 2021; Saccente and Woods, 2010; Smith and Kauffman, 2010). All have limited utility in diagnosing acute disease, since antibodies are produced 50–70 days after the onset of symptoms (Linder and Kauffman, 2021; Klein et al., 1987). In addition, these antibodies can remain for a year or more even after the patient is cured. Assays for the detection of antibodies against W-1 wall antigen of *Blastomyces dermatitidis* have been evaluated with promising results, but the tests are not commercially available (Linder and Kauffman, 2021; Soufleris et al., 1994).

Aspergillosis

In the case of aspergillosis, serological tests such as ID are essential to confirm a clinical picture both of aspergilloma and allergic bronchopulmonary aspergillosis, provided that the results, even when the titers obtained are low, can be compared with the patient's symptoms. IgG antibodies are detected and it is necessary to combine it with radiological studies (Pfeiffer and Wong, 2015; Reviákina et al., 2007).

Detection of fungal antigens

Antigen detection is extremely useful in the diagnosis of many fungal diseases, especially in immunosuppressed patients (Quindós, 2015). A variety of immunological techniques including latex particle agglutination (LA), EIA, and lateral flow assay (LFA) are used to identify antigenic components in a clinical specimen, and often require mono- or polyclonal antibodies to detect the antigen. Its main limitations are cross-reactions, the transience of antigens in some hosts, and the lack of specificity for a particular antigen (Pfeiffer and Wong, 2015).

Candidiasis

The cell wall mannan of *Candida* spp. is an antigen that can be detected in the serum of patients with invasive candidiasis, which in turn is rapidly degraded and eliminated from the bloodstream. The detection of mannan by EIA is a test that has been commercially available for years (Platelia Candida Ag Plus[®], Bio-Rad), but, due to its poor diagnostic performance, its use in parallel with the detection of anti-mannan antibodies is recommended (Platelia Candida Ab Plus[®], Bio-Rad), in those patients with suspected invasive candidiasis (Freeman Weiss et al., 2021; Sendid et al., 1999).

A recent review of the usefulness of these tests in oncohematological patients with invasive candidiasis showed that the combined detection of mannan and anti-mannan antibodies had a sensitivity of 83% with a specificity of 86%, these tests being faster than the blood culture (Mikulska et al., 2010). Furthermore, these tests have also shown their usefulness in neutropenic patients, due to their high negative predictive value of 95% (Ellis et al., 2009). The results vary depending on the *Candida* spp. involved in invasive candidiasis, being more useful when they are produced by the *Candida albicans* species complex, *Candida glabrata* species complex and *Candida tropicalis* than by the *Candida parapsilosis* and *Candida krusei* species complexes (Pemán et al., 2017).

Aspergillosis

Galactomannan (GM) is a cell wall polysaccharide component of *Aspergillus* spp. that is released during invasion into tissues. It can be detected in serum, BAL, biopsies, urine, CSF, pericardial fluid and pleural fluid of patients with invasive aspergillosis (Pemán et al., 2017; Pfeiffer and Wong, 2015).

Its detection in serum has been commercialized by means of a sandwich EIA (Platelia Aspergillus[®], Bio-Rad), which uses a monoclonal antibody capable of detecting low levels of GM in blood. It is an alternative diagnostic technique in front of culture (results in 4 h), that is rapid, simple and reproducible, which has been included as a mycological criterion in the consensus definitions of the European Organization for Research and Treatment of Cancer/Mycoses Study Group of the National Institute of Allergy and Infectious Diseases (EORTC/MSG) for neutropenic patients (de Pauw et al., 2008; Donnelly et al., 2020), has been approved by the FDA and has sensitivity and specificity values of 81% and 89%, respectively (Wheat, 2003), making it a useful test for the diagnosis and monitoring the disease.

The GM values do not have the same diagnostic utility in non-neutropenic patients, especially with solid organ transplantation. A meta-analysis has shown that in high-risk patients the sensitivity values of the test in serum decrease to 61% with a specificity of 93% in both cases of probable and possible invasive aspergillosis, while in proven cases the sensitivity of the test

is found around 71–79% (Pfeiffer et al., 2006). In critically ill patients with pneumonia, neutropenic, hemato-oncological and immunosuppressed, it has proven to be very useful (Meersseman et al., 2008; Pfeiffer et al., 2006).

It is important to note that false positive results can be obtained due to cross reactions with other species of fungi (*Penicillium* spp., *Alternaria* spp., *Paecilomyces* spp., and *Cryptococcus* spp.), during treatment with antibiotics totally or partially derived from fungi (piperacillin-tazobactam, amoxicillin-clavulanic acid) and in neonates with intestinal colonization by *Bifidobacterium* spp. (Duarte et al., 2014; Marr et al., 2005; Pemán et al., 2017; Pfeiffer and Wong, 2015). False negative results are rare but can also be obtained due to a low fungal burden, as occurs in invasive aspergillosis caused by the *Aspergillus fumigatus* complex, the use of prophylactic antifungals, and high antibody titers (Hachem et al., 2009; Mennink-Kersten et al., 2004; Pfeiffer and Wong, 2015).

The Platelia Aspergillus® test was approved by the FDA for use in BAL in 2011, improving the sensitivity of the test when compared with the results obtained in serum in patients with risk factors for invasive aspergillosis (D' Haese et al., 2012; Husain et al., 2008), with sensitivity values of 87% and specificity of 89% (Zou et al., 2012) and sensitivity and specificity of 82% and 97%, respectively (Avni et al., 2012), where the diagnostic performance of the test depends on the cutoff value selected for positivity, being 0.5 the one approved by the FDA. To increase diagnostic performance, serial determinations are recommended: GM values >0.5 in two consecutive sera increase the specificity and positive predictive value of the test; if a single determination is made, a GM value >0.7 is considered positive. GM values in BAL >0.5–1 are considered diagnostic criteria for probable invasive aspergillosis. It is important to note that the assay is currently only validated for serum and BAL specimens. The test has also proven to be very useful for monitoring response to treatment, where the decrease in GM values predicts a satisfactory response with patient recovery (Chai et al., 2012; Koo et al., 2010).

The latest recommendations of the EORTC/MSG group for the use of GM establish different cutoff values for the test adjusted to the clinical specimen, independent of the patient group, which differ from the cutoff value recommended by the manufacturer and approved by the FDA (0.5), and the validated clinical samples (serum and BAL): Single serum or plasma: ≥ 1.0 ; BAL fluid: ≥ 1.0 ; Single serum or plasma: ≥ 0.7 and BAL fluid ≥ 0.8 ; CSF: ≥ 1.0 (Donnelly et al., 2020; D' Haese et al., 2012; Leeflang et al., 2015; Mennink-Kersten et al., 2004). Según los reportes de algunas investigaciones, la detección de GM en plasma y LCR pueden avalar el diagnóstico de IA (Chong et al., 2016; Klont et al., 2004).

In 2008, the first version of the LFA was commercialized for the diagnosis of invasive aspergillosis, which had sensitivity and specificity values with serum samples of 68% and 87%, respectively, and of 86% and 93% with BAL samples respectively (Pan et al., 2015; Thornton, 2008). Recently, the version of the IMMY Sona Aspergillus Galactomannan LFA has been released, which using BAL and serum samples and has sensitivity and specificity values of 83–92% and 91–92%, respectively (Lass-Flörl et al., 2019; Mercier et al., 2020).

Cryptococcosis

The detection of glucuronoxylomannan (GXM), the polysaccharide antigen present in the capsule of the *Cryptococcus neoformans* and *C. gattii* species complexes, is one of the most useful alternative diagnostic methods to culture in medical mycology. It is included by the EORTC/MSG as a diagnostic criterion for cryptococcosis (de Pauw et al., 2008; Donnelly et al., 2020) and is very useful for the diagnosis in patients with HIV and meningeal cryptococcosis (scientific evidence AI) and in oncohematological patients with meningeal and disseminated cryptococcosis (scientific evidence A-II) (Ayats et al., 2011; Marchetti et al., 2011). Currently for the detection of this antigen there are several commercial tests such as LA, EIA techniques that use mono and polyclonal anti-glucuronoxylomannan antibodies (Ayats et al., 2011) and the Point-of-Care LFA; the latter recently designed and approved by the FDA in 2011 (IMMY, Norman, OK, United States) (Lindsley et al., 2011).

The diagnostic performance of the LA and EIA tests depends on the immune status of the patient, the clinical specimen (serum or CSF) and the clinical form of the disease (localized or disseminated) to diagnose cryptococcal meningitis, since it usually varies. Using serum and CSF, the sensitivity of the titers was 92% and 99% in patients with HIV; 88% and 100% in transplant recipients; 87% and 97% in immunosuppressed patients, and 92% in CSF of immunocompetent patients (Antinori et al., 2005). The prognostic value of the titers is controversial, due to the problems mentioned above. There are studies that associate higher initial titers with increased mortality and relapses, while other studies have not confirmed this association (Chen et al., 2012; Lin et al., 2009; Mitchell and Perfect, 1995; Pappas et al., 2001; Singh et al., 2008). The use of titers to control the therapeutic response is also controversial, since it has been reported that their use is not recommended, especially in patients with HIV (Perfect et al., 2010; Powderly et al., 1994). In particular, LFA has excellent diagnostic performance in serum and outstanding in CSF, when compared to other techniques. Among its advantages are that is easy and fast to perform and interpret, in addition to its easy storage at room temperature, however, it is necessary to validate the titers of the cryptococcal antigen before adopting the test for generalized use (Binnicker et al., 2012; Hansen et al., 2013; McMullan et al., 2012). The sensitivity of all the tests, regardless of the patient group, was much better in serum and CSF (94%) than India ink (60%), but similar to CSF culture (92%) (Antinori et al., 2005).

Other clinical samples such as pleural fluid and urine may be useful in certain situations for the diagnosis of cryptococcosis (Lindsley et al., 2011; Young et al., 1980). Among the limitations of these tests are false negative results, which although occasional, can occur in the face of a very low burden of the fungus in clinical specimens. False positive results are rare, but can occur in patients with *Trichosporon* spp., *Stomatococcus* spp. and *Capnocytophaga canimorsus* infections (Chanock et al., 1993; McManus and Jones, 1985; Pemán et al., 2017; Westerink et al., 1987), as well as in patients with rheumatoid factor, some neoplasms, specimen contamination during its manipulation and by the use of silicone tubes to store the specimen (Pemán et al., 2017).

Histoplasmosis

The detection of a polysaccharide antigen of *Histoplasma capsulatum* by EIA is of great diagnostic utility as an alternative test to culture. Depending on the clinical manifestation of histoplasmosis, the antigen may be present in urine, serum, plasma, CSF or BAL. Currently, there are commercial tests such as the MVista Histoplasma[®] (MiraVista Diagnostics, Indianapolis, IN, United States), a quantitative sandwich EIA that uses rabbit polyclonal anti-histoplasma antibodies (Connolly et al., 2007), the Histoplasma Antigen ELISA[®] (YMMI, Norman, OK, United States) approved by the FDA for in vitro diagnostics, and a test developed by the Centers for Disease Control (CDC) for resource-poor countries (Linder and Kauffman, 2021; Scheel et al., 2009; Zhang et al., 2013).

These tests are useful for diagnosing histoplasmosis in HIV patients with progressive disseminated disease (scientific evidence A-II), being less useful for the diagnosis of the disease in patients without HIV (scientific evidence B-II). Antigen detection is more sensitive with urine samples (80–90%) than in serum (50–80%). In patients with pulmonary histoplasmosis without immunodeficiencies the use of BAL is recommended, with a diagnostic sensitivity of 93% (scientific evidence A-II) (Hage et al., 2010). These tests are also useful for the therapeutic monitoring of the disease, since antigen levels decrease with appropriate therapy while increase with relapse (Linder and Kauffman, 2021).

False negative results may occur, depending on the group of patients and the severity of the disease. Cross-reactivity commonly occurs with paracoccidioidomycosis, blastomycosis, and penicilliosis; is less common with coccidioidomycosis, and rare with aspergillosis (Linder and Kauffman, 2021; Pfeiffer and Wong, 2015).

Paracoccidioidomycosis

For the diagnosis of this disease in immunosuppressed patients several antigen detection techniques have been developed. The most widely used is gp43 antigen, which can be detected by an immunoblotting technique in urine samples with excellent sensitivity and specificity values (Salina et al., 1998) and with an EIA technique, which uses monoclonal antibodies to detect this antigen in clinical specimens of serum, urine, CSF and BAL from patients with both confirmed acute and chronic forms of paracoccidioidomycosis (Marques da Silva et al., 2003). The usefulness of gp70 antigen detection for the diagnosis of this endemic mycosis has also been demonstrated (Marques da Silva et al., 2004a). These tests are also useful for the therapeutic follow-up of the disease (Marques da Silva et al., 2004b).

Blastomycosis

For the alternative diagnosis of this mycosis, a commercial quantitative antigen detection test is available in urine, serum, plasma, CSF and BAL specimens (MVista Blastomyces Antigen ELISA[®]; MiraVista Diagnostics, Indianapolis, IN, United States), which detects a glycoprotein that is unfortunately not gender specific; therefore, the specificity of the test is high for patients without fungal disease and presents similar cross-reactions to the MVista Histoplasma[®] test (MiraVista Diagnostics, Indianapolis, IN, United States). The test has a high sensitivity for the detection of antigen in urine samples (85–73%) (Bariola et al., 2011; Connolly et al., 2012; Durkin et al., 2004; Linder and Kauffman, 2021). Its use is not recommended for the therapeutic monitoring of the disease, since no correlation has been established between antigen levels and treatment response (Linder and Kauffman, 2021; Pfeiffer and Wong, 2015).

Coccidioidomycosis

Commercially there is an EIA test for the detection of the *Coccidioides* species complex antigen (MVista Coccidioides[®], MiraVista Diagnostics, Indianapolis, IN, United States), which has shown a sensitivity of 71% and a specificity of 99% in urine samples from immunosuppressed patients with moderate to severe disease; however, cross-reactivity with other endemic mycoses such as histoplasmosis and paracoccidioidomycosis was observed (Durkin et al., 2008). In serum and urine samples from patients with mild disease, the sensitivity of the test was 73% in serum and 50% in urine, with a specificity of 100%, but the test was evaluated in few cases (Durkin et al., 2009).

Penicilliosis

In patients with HIV and AIDS, studies carried out for the detection of *Penicillium marneffei* antigen by EIA tests have shown sensitivity and specificity values greater than 90%. The test has not yet been commercialized (Chaiyaroj et al., 2003).

Detection of metabolites or structural components

For the detection of fungal metabolites, which behave as biomarkers for the diagnosis of invasive fungal diseases, techniques such as gas chromatography and enzymatic reactions are used. These biomarkers are not unique to particular fungal species, so this is a major limitation when using them for diagnosis.

Panfungal 1,3- β -D-glucan assay (BG)

This is a cell wall structural component of various fungi that is released into the blood during the course of fungal infection. It is a non-specific panfungal biomarker and any positive result must be confirmed by other mycological techniques to identify the fungus causing the infection. In this test, the experience of the laboratory professional in charge of the diagnosis is decisive for the interpretation of the results, since it is a complex test. Four assays are currently commercially available, each with individual cutoff values for test positivity: Fungitell (formerly Glucatell; Associates of Cape Cod, East Falmouth, MA), Fungitec-G (Seikagaku, Tokyo, Japan), assay Wako turbidimetric test (Wako Pure Chemical Industries, Tokyo, Japan) and Maruha colorimetric test (Maruha-Nichiro Foods, Tokyo, Japan) (Lamoth et al., 2012). A threshold >80 pg/mL with Fungitell is valid for the diagnosis;

there is insufficient evidence to use tests produced by other manufacturers (White et al., 2019). More recently, the Associates of Cape Cod, responsible for the Fungitell BG assay, developed the Fungitell STAT™ assay, that permits simple, rapid (<1 h) testing (D'Ordine et al., 2020; White and Price, 2021).

The detection of this component has been evaluated for the diagnosis of *Pneumocystis jirovecii* pneumonia (PCP) with excellent results. Two meta-analyses studied its diagnostic precision, finding sensitivity and specificity values of 96% and 84%, respectively (Onishi et al., 2012) and of 95% and 86% (Karageorgopoulos et al., 2013). Both studies evaluated the use of a single blood BG determination and, given the high sensitivity of the test, it is considered that it may be effective in excluding a diagnosis of PCP without the need for bronchoscopy.

For the panfungal diagnosis of invasive fungal infections, with the exception of PCP, the BG test is considered to have moderate utility, with sensitivity values between 77% and 80% and specificity between 82% and 85%, based on the EORTC/MSG definitions (Karageorgopoulos et al., 2011), and it has been included as a diagnostic criterion in the definitions of invasive fungal disease (de Pauw et al., 2008; Donnelly et al., 2020) and in the therapeutic guidelines of the ESCMID (Cuenca-Estrella et al., 2012). Its greatest limitation is the inability of the test to differentiate between different fungi species. Although BG is found in the cell wall of *Candida* spp., *Aspergillus* spp., *Pneumocystis jirovecii*, *Trichosporon* spp., *Fusarium* spp. and *Saccharomyces* spp., this component is not found in *Cryptococcus* spp. nor in the causative agents of mucormycosis. If the BG test is negative, the probability that the patient has an invasive fungal infection is quite low, so its negative predictive value is high. False positive results may occur associated with recent surgeries, hemodialysis, bacteremia, use of antibiotics such as amoxicillin-clavulanic acid, antifungals such as anidulafungin, and products such as immunoglobulins or albumin (Hanson et al., 2012; Kanamori et al., 2009; Marty et al., 2006; Mennink-Kersten et al., 2006, 2008; Mohr et al., 2011; Pickering et al., 2005).

D-arabinitol detection

D-arabinitol (DA) is a metabolite produced by the pathogenic *Candida* species, with the exception of *Candida krusei* and *Candida glabrata*, which is found in the serum of patients with invasive candidiasis, and makes it a diagnostic marker for this disease. Currently there are two techniques for its measurement: gas chromatography, which is very laborious and is not available in hospital laboratories, and the commercial enzymatic technique developed in Japan (Arabinitec-Auto, Marukin Diagnostics, Osaka, Japan), for serum samples and urine. Some studies have shown that DA can be detected earlier than *Candida* growth in blood cultures and that it is a good marker for monitoring clinical response to treatment (Hino et al., 2000; Yeo et al., 2006; Walsh et al., 1995).

Mannitol detection

It is an acyclic polyol produced in large quantities by different fungi, including *Aspergillus* spp. and *Cryptococcus* spp. Unfortunately, the available data do not support its usefulness as a diagnostic marker for invasive diseases produced by these two genera (Pfeiffer and Wong, 2015).

There are currently no metabolite screening tests for histoplasmosis, blastomycosis, coccidioidomycosis, and paracoccidioidomycosis.

Protein detection by MALDI-TOF MS

Matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF MS) is a recently developed biophysical method in the field of clinical microbiology, which significantly reduces the time necessary for the identification of fungi in the routine diagnostic process of the laboratory, due to the speed with which this procedure is carried out (Freeman Weiss et al., 2021; Romanelli and Wickes, 2015).

MALDI-TOF MS identifies yeasts and filamentous fungi after their recovery from the culture of clinical samples on solid media in few minutes, through the unique protein mass spectrum of each species, comparing it with the reference spectra library that is linked to the measuring instrument (Becker et al., 2014; Freeman Weiss et al., 2021; Lau et al., 2013; Marklein et al., 2009; Rychert et al., 2017; Sanguinetti and Posteraro, 2016; Sendid et al., 2013). Obtaining fungal isolates from cultures is an important limitation to be taken into consideration for identification, since the ideal is to be able to identify fungi directly in the original clinical sample. Some research groups have developed methods for the direct identification of fungi with variable success rates (Becker et al., 2014; Ferreira et al., 2011; Ferroni et al., 2010; Rychert et al., 2017; Sanguinetti and Posteraro, 2016). A recent study conducted with yeast positive blood cultures reported that direct identification with MALDI-TOF using blood cultures yielded 95.9% correct identifications for *Candida albicans* and 86.5% for non-*Candida albicans* species, when comparing its diagnostic performance with the conventional culture-based method (Spanu et al., 2012). This suggests that direct identification of *Candida* spp. directly from blood cultures is feasible and could become a standard procedure, but large-scale evaluations are still needed to confirm this, as some yeast require additional processing and repeated analysis.

There are currently several mass spectrometric identification systems commercially available. The Bruker Daltonics system (Billerica, MA) includes a mass spectrometer along with software plus a database called "Biotyper". The Shimadzu Axima Assurance system (Columbia, MD) uses a mass spectrometer, the Launchpad software, and the AnagnosTec GmbH database (SARAMIS). The latter was recently acquired by the bioMérieux trademark and is currently called "VITEK MS" (Freeman Weiss et al., 2021; Romanelli and Wickes, 2015; Rychert et al., 2017).

MALDI-TOF depends on its reference spectra library, which is proprietary to the commercial system (there is no public spectra base), although users can add spectra to expand it, however, this is an important limitation, since it would take a long time to create

a spectra library similar to the molecular sequence databases that exist today (Freeman Weiss et al., 2021; Romanelli and Wickes, 2015). Other important limitations lie in the fact that some closely related fungi cannot be differentiated with these systems and that the morphological variety may require different sets of proteins, which will result in variable spectra for identification, which is a challenge for these systems. Furthermore, the cutoff points for identification may vary between fungi.

These systems are not yet approved by the FDA, limiting their widespread use in the United States. Although MALDI-TOF still needs improvement, it is a promising technology as it is an automated system that has high throughput and fast response time, much needed in the laboratory when it comes to fungal identification. In addition, it can be used for the identification of bacteria and mycobacteria, which makes it an instrument that can bring great benefits to the routine microbiology laboratory (Romanelli and Wickes, 2015).

Nucleic acid detection

Fungal DNA detection techniques using polymerase chain reaction (PCR) have great diagnostic sensitivity, being able to detect minimal concentrations of DNA in clinical samples, however, their major limitations are that they are highly developed and standardized in individual studies (in house), which makes their transfer to routine microbiology laboratories very difficult, and implies the need for validation in multicenter studies (Pemán et al., 2017; Quindós, 2015).

Nested PCR (nPCR), using the Hcp100 gene region as a target, is one of the most widely used techniques for the diagnosis of histoplasmosis, with sensitivity values between 70% and 100% and specificity between 90% and 100%, which depend on the analyzed clinical sample, where the most used are fresh biopsies, paraffin-embedded biopsies, respiratory samples, bone marrow, CSF, serum and whole blood (Bialek et al., 2002; García et al., 2017; Linder and Kauffman, 2021; Maubon et al., 2007; Muñoz et al., 2010; Toranzo et al., 2009). Because the most important disadvantage of this technique is the possibility of contamination by amplicons, it is necessary to use biological safety cabinets during the preparation of the reagent mixtures and the addition of the templates to be used during the first and second rounds of PCR, processes that make it difficult to transfer the technique to routine microbiology laboratories (García et al., 2017; Toranzo et al., 2009). However, because it reduces diagnosis time, it has become a complementary technique to direct examination, culture and serological tests, especially in patients with HIV and other immunodeficiencies (García et al., 2017; Simon et al., 2010).

Quantitative PCR (qPCR), using the ITS1 region of the rRNA as a target, is another of the most widely used techniques for the diagnosis of histoplasmosis, showing sensitivity values between 78% and 100% and specificity between 98% and 100%, in respiratory samples, biopsies, CSF, bone marrow, serum and whole blood. DNA quantification allows monitoring of clinical outcome, but it is a technique that requires expensive reagents and equipment, so it is not accessible to routine microbiology laboratories, especially in low-resource countries, where histoplasmosis is often an endemic disease (Buitrago et al., 2007; Linder and Kauffman, 2021; Simon et al., 2010). In a multicenter Latin American study, seven protocols for nPCR and qPCR were evaluated with different concentrations of *Histoplasma capsulatum* DNA, reporting global sensitivity and specificity values of 86% and 100% respectively, showing that the protocols and techniques were reproducible, sensitive and specific (Buitrago et al., 2013).

Molecular methods for the diagnosis of coccidioidomycosis are used for species identification and for diagnosis from clinical samples. PCR technique based on the amplification of antigen 2/proline-rich antigen has been used for the identification of *Coccidioides posadasii* (Bialek et al., 2004; Canteros et al., 2009) and also in clinical samples of patients with this disease (Canteros et al., 2010).

In recent years, alternative techniques to staining and immunofluorescence have been developed for the diagnosis of PCP, based on the detection of fungal DNA using nPCR and qPCR-RT. Direct immunofluorescence assay (DIF) is currently considered the preferred technique for the diagnosis of PCP due to its high sensitivity and specificity (Choe et al., 2014; Cruciani et al., 2002; Panizo et al., 2008). However, the PCR has proven to be more sensitive in detecting *Pneumocystis jirovecii* than the aforementioned stains. The differentiation between colonization and infection using this technique requires that its results be interpreted with caution, taking always into account the patient's symptomatology, since it can detect this fungus in asymptomatic patients (Casanova et al., 2006; Panizo et al., 2008, 2009, 2020; Tomás and Matos, 2018).

It has been demonstrated that nPCR is more sensitive for the detection of *Pneumocystis jirovecii* than stains and even than DIF. The primers described by Wakefield et al. were chosen because the mitochondrial large subunit rRNA (mtLSUrRNA) gene is the most specific and sensitive for the detection of this fungus, with a detection threshold that can reach values of 0.5–1 organism/μL of specimen. The mtLSU rRNA is a multicopy gene in the *Pneumocystis jirovecii* genome that contributes to the higher successful amplification rates, especially when used with nPCR. For this reason, this technique produced less false negative results and presented higher concordance with the results of conventional stains and DIF (Tomás and Matos, 2018; Wakefield et al., 1990, 1991).

Currently, the technique of greatest clinical applicability for the diagnosis of PCP is qPCR-RT in samples of induced sputum and BAL, since it allows distinguishing colonization from infection by establishing a cutoff value. In patients with HIV, the sensitivity and specificity values of this test exceed 95%, while in patients without HIV the sensitivity is slightly lower, but the negative predictive value is 98%, therefore, in this type of patients, a negative result with this technique rules out the presence of the disease (Azoulay et al., 2009; Huggett et al., 2008).

The detection of nucleic acids has been extensively investigated for invasive aspergillosis (IA), however, it has not been possible to clarify yet the type and volume of sample to use, the best DNA extraction method, the best target and the meaning of a positive result (Duval et al., 2008). The sensitivity and specificity values are highly variable, being between 88% and 75%, respectively (Mengoli et al., 2009).

The European *Aspergillus* PCR Initiative working group from the International Society for Human and Animal Mycology (ISHAM) has attempted to standardize the variables of the PCR technique and define a set of recommendations, rather than a standard PCR assay for the molecular diagnosis of AI. Among the standardized conditions, they suggest using serum samples and including internal controls (White et al., 2011a,b).

In-house techniques have great variability in their sensitivity and specificity values, making their comparison difficult due to the lack of standardization and validation, both for the methods and their results, therefore, their generalized use has a limited recommendation as an alternative for the diagnosis of fungal diseases (scientific evidence B-II and B-III) (Ayats et al., 2011). For these reasons, the use of qPCR assays, which are already commercialized, has been proposed, such as Film Array® (BioFire, United States), LightCycler® SeptiFast Test M GRADE (Roche Molecular Diagnostics, United States), Lumindex xTAG® Fungal ASR (Luminex Molecular Diagnostics, United States), MycAssay® *Aspergillus* and MycAssay® *Pneumocystis* (Myconostica, Great Britain), Magi-plex™ Sepsis (Seegene, South Korea), Sepsis-Test™ (Molzym GmbH & Co., Germany) and VYOO®/LOOXSTER® (SIRS-Lab, Germany).

MycAssay® *Aspergillus* has been evaluated in patients hospitalized in intensive care units and in patients with high-risk hematological diseases. In the first group of patients, the sensitivity values were between 86.7% and 100%, especially when using multiple samples, while the specificity values were between 87.6% and 92.9% (Torelli et al., 2011; Guinea et al., 2013). For the second group of patients, the sensitivity values ranged between 50% and 80% and the specificity values between 90.5% and 100% (White et al., 2011a,b). The results published with the use of MycAssay® *Pneumocystis* have been encouraging using BAL samples, reaching sensitivity and specificity values of 100% (McTaggart et al., 2012).

Blood fungal DNA detection techniques such as LightCycler® SeptiFast Test M GRADE, SepsisTest™ and Film Array® detect common pathogens such as *Candida* spp. and *Aspergillus fumigatus*, however, according to the few published studies, although preliminary results are promising, its usefulness in the diagnosis of invasive fungal diseases has not been determined (Pernán et al., 2017). According to research reports carried out in febrile neutropenic patients, the LightCycler® SeptiFast Test M GRADE showed limited sensitivity and specificity values (Lamoth et al., 2010; von Lilienfeld-Toal et al., 2009), therefore, its use is still not highly recommended for the diagnosis of these diseases.

For the diagnosis of invasive candidiasis, the FDA approved T2Candida panel appears to show promise in the detection of *Candida* spp. in whole blood and has already been evaluated in a clinical trial (Beyda et al., 2013), including as mycological evidence to support the diagnosis of probable candidemia (Clancy and Nguyen, 2018; Donnelly et al., 2020). The test has a high negative predictive value, but its positive predictive value varies depending on the prevalence of the disease in specific patient groups (White and Price, 2021; Clancy et al., 2018; Mylonakis et al., 2015). Fungal DNA amplification in tissue combined with sequencing, when yeasts have been observed in formalin-fixed and paraffin-embedded tissue biopsies are the recommended complementary techniques for the diagnosis of proven invasive candidiasis (Donnelly et al., 2020).

Fluorescence in situ hybridization using peptide nucleic acid probes (PNA-FISH) (AdvanDX, Woburn, MA) has been used in some clinical microbiology laboratories to discriminate *Candida albicans* from non-*Candida albicans* directly from positive blood cultures (Pulcrano et al., 2013; Stone et al., 2013). The assay uses PNA probes to target specific rRNA sequences in a highly sensitive and specific FISH assay (Rigby et al., 2002). The probe is capable of discriminating between *Candida albicans* and *Candida dubliniensis*, which is impossible to do at the phenotypic level (Lau et al., 2009).

There are variations of conventional PCR techniques that have been shown to be useful for mycological diagnosis. One of them is nucleic acid sequence-based amplification (NASBA). This isothermal amplification technique has numerous advantages, since it amplifies RNA templates that are abundant for some targets (for example rRNA). A commercial version of this technology has been available for several years (AccuProbe, Hologic Gen-Probe Inc., San Diego, CA) and has been used to detect *Histoplasma capsulatum*, *Coccidioides immitis*, and *Blastomyces dermatitidis* (Chemaly et al., 2001; Romanelli and Wickes, 2015; Scalarone et al., 1992; Valesco and Johnston, 1997).

A second type of isothermal PCR is called loop-mediated isothermal amplification LAMP (Notomi et al., 2000). The key component of this reaction is a DNA polymerase derived from *Bacillus stearothermophilus* (Njiru, 2012). LAMP has been used successfully to detect several fungi, including *Fusarium* spp., *Cryptococcus* spp. and *Aspergillus* spp. (Denschlag et al., 2012; Lucas et al., 2010; Niessen, 2013; Sun et al., 2010). Rolling circle amplification (RCA) is a third type of isothermal amplification that results in massive amplification of target sequences (Fakruddin et al., 2013). This technology uses DNA polymerase from the bacteriophage Phi29 to amplify a DNA template. It is a sensitive technique to identify fungal genera that are difficult to differentiate at the species level, even with molecular methods, due to the highly conserved target sites (Sun and de Hoog, 2013). RCA has been used to detect a variety of fungi, including *Penicillium marneffei*, *Fonsecaea* spp. and *Exophiala* spp. (Najafzadeh et al., 2011, 2013; Sun et al., 2011).

In addition to these technologies, there are other PCR-based methods that have various applications in mycological diagnosis and epidemiology. One of them is random amplification of polymorphic DNA (RAPD). Genetically unrelated strains will have different RAPD patterns, depending on how quickly their genomes evolved from each other during geographic isolation and the frequency of the primer site in the genome. This method has been extensively studied for *Cryptococcus neoformans* and has been developed as a strain typing tool (Meyer et al., 1999). It has also been used for the identification of *Aspergillus fumigatus* and *Candida albicans* strains. The technique is not routinely used as an identification tool in microbiology laboratories because it is highly susceptible to variations; however, it is very useful for investigating outbreaks.

The PCR technique with Restriction Fragment Length Polymorphism (RFLP) is based on the use of restriction enzyme digestion of gene amplification products or polymorphic DNA sequences. It allows the study of a very limited region of the genome (specific genes that code for special proteins) and accurately identifies microorganisms. Its power of discrimination and reproducibility may

be somewhat lower than that of other identification methods, since this technique depends on factors such as the fungus species, the analyzed gene and the restriction enzyme to be used, but the power of discrimination increases using various restriction enzymes. This technique is quick, easy, and the restriction patterns are highly reproducible, and have been used for the identification of *Cryptococcus* spp., *Fonsecaea* spp. and *Candida* spp. (Bonifaz, 2012; Escandón et al., 2006; Ferrara et al., 2018; Moreno et al., 2017; Sidrim et al., 2010).

The sequencing of genetic material is the most accurate tool to establish the identification of any fungus. Easy access to public databases such as GenBank and search algorithms such as BLAST programs (Altschul et al., 1990), allow users to query an unknown sequence and obtain an identification result by comparison and analysis of the sequences.

Identifying fungi based on their sequence is expensive and requires specialized personnel and equipment. All this means that these types of studies are not easily available for most routine microbiology laboratories and are only accessible in research centers. One of the great challenges of these diagnoses has been how to better standardize the methods used to get identification and adjust these guidelines to a clinical laboratory daily operation. Currently, the most useful guidelines are provided by the Clinical Laboratory Standards Institute, which describe in detail sequence-based identification of fungi and the targets that can be used (Petti et al., 2008).

Introduction to transmissible spongiform encephalopathies

Prions are atypical infectious agents that have puzzled researchers dealing with transmissible spongiform encephalopathies (TSE) since their discovery, primarily due to the absence of nucleic acids in their composition. TSE or prionopathies are a group of rapidly progressing, invariably fatal neurodegenerative diseases which affect several mammals including humans (Prusiner, 1984). Although scrapie, a sheep prionopathy, has been documented since the 18th century (Liberski, 2012) and another TSE affecting humans, Creutzfeldt-Jakob disease (CJD), was described in 1920 (Creutzfeldt, 1920), the nature of the causal agent of such diseases was not identified until 1982. On this year Stanley Prusiner proposed the “protein-only” hypothesis (Prusiner, 1982) which, in the year 1997, granted him the Nobel Prize in Physiology and Medicine. This revolutionary theory proposed that TSE were caused by an infectious agent completely devoid of nucleic acids and exclusively composed by a protein which he named prion (proteinaceous infectious particle). Taking into account that all other pathogens known in 1982 based their existence on nucleic acids, the “protein-only” hypothesis was highly controversial. However, since Prusiner’s theory was first published, a growing body of evidence has been gathered supporting the existence of an exclusively proteic novel infectious pathogen. Nowadays, the fact that TSE are caused by prions is widely accepted (Soto, 2011).

The prion protein (PrP) is the major, if not the only, component of prions. As per the “protein-only” hypothesis, prions are constituted by an aberrantly folded isoform (PrP^{Sc}, from scrapie) of the natively folded or cellular prion protein (PrP^C) (Stahl and Prusiner, 1991). PrP^C is a relatively small glycoprotein of unknown function, expressed most abundantly in the outer membranes of cells from the central nervous system (CNS) and lymphoreticular system. It is bound to the membrane through a glycosylphosphatidylinositol (GPI) anchor (Stahl et al., 1991). PrP^C is a highly conserved protein in mammals, comprised of two regions: an unstructured and flexible N-terminal tail, and a globular C-terminal domain which hosts three α -helices and a short, two-strand β -pleated sheet (Lysek et al., 2005). Upon a thus far poorly characterized misfolding event, it gives rise to the PrP^{Sc}, acquiring pathogenic characteristics. In contrast to PrP^C, prions are aggregation-prone, water insoluble proteins, partially resistant to degradation or physicochemical treatments. This, in combination with their ability to impose their aberrant conformation onto their natively folded counterparts, leads to the formation of amyloid aggregates or deposits (Telling et al., 1996). Moreover, this self-replicative protein also shows neurotoxic properties that lead to neuronal death and the rapidly evolving neurodegeneration that characterizes prionopathies (Brandner et al., 1996).

Despite the apparent simplicity of the causal agent of prion diseases compared to other infectious pathogens, their etiology and the clinical manifestations of TSE are highly heterogeneous. Prionopathies can be acquired through ingestion or introduction, by iatrogenic means, of exogenous PrP^{Sc}. This causes what is known as the acquired form of the disease. The exogenous PrP^{Sc} then propagates inducing its conformation onto the endogenous PrP^C. Alternatively, familial or hereditary forms of TSE develop due to the presence of mutations in the gene encoding the PrP^C protein (PRNP), which increase the protein’s misfolding proneness into PrP^{Sc} (Prusiner, 1993). Once generated, this PrP^{Sc} will initiate an autopropagative process which recalls the one occurring in exogenously acquired TSE, leading to the development of a genetic prionopathy. Moreover, prion diseases can also arise sporadically, purportedly due to a low-frequency event of spontaneous misfolding of the wild type PrP^C. This latter type is in fact the most common form of prion disease in humans, accounting for 85–90% of the cases. In contrast, genetic forms make up for around 15–10% of cases and acquired forms have almost been eradicated in humans (WHO, 2003).

Despite being out of the scope of this article, it is worth mentioning the most common animal prion disorders. When it comes to detecting prions in animals, simplicity and cost-effectiveness of the methods applied are key, however, some of these relatively simple methods have been further developed and refined for human prion disease detection in clinical settings. Therefore, despite mainly referring to human prion detection methods, we will also include a few comments on techniques used for animal prion detection. Scrapie in sheep and goat, bovine spongiform encephalopathy (BSE) in cattle, and chronic wasting disease (CWD) in

deer, are nowadays the only naturally occurring prion diseases in animals (Imran and Mahmood, 2011). Nonetheless, due to their potential impact in public health and in the ranching industry, as sadly proven by the mad cow disease crisis caused by the zoonotic capacity of BSE-causing prions (Knight, 1999), most developed countries have implemented surveillance programs to systematically detect cases and prevent outbreaks (Bonetta, 2000; Bird, 2003). Other prion diseases in animals have been reported such as transmissible mink encephalopathy (TME), feline spongiform encephalopathy (FSE) and exotic ungulate spongiform encephalopathy (EUE), although in these cases BSE or scrapie prion ingestion is thought to be the cause of the disease (Imran and Mahmood, 2011). Finally, susceptibility of many other mammalian species to prion infection has been demonstrated in laboratory animals. Mainly in non-human primates and in rodents, derived from human prion or other naturally occurring animal prion inoculation (Brandner and Jaunmuktane, 2017).

This review will center on human TSE clinical and histopathological diagnosis, as well as on other methods developed for prion detection in tissues and body fluids or disease-associated biomarker screening. For that purpose, it is first important to get some insight into the different human prion diseases and some specific features of these proteinaceous pathogens, such as their interspecific transmission ability and the strain phenomenon. Several prion diseases have been described in humans, each distinguished by distinct clinical manifestations and neuropathological hallmarks, which are due to differential biochemical features of the misfolded prion protein causing each disease. This variability is due to the unprecedented capacity of prions to, despite sharing the same protein sequence, adopt slightly different conformations known as prion strains (Aguzzi, 1998). Reminiscent of viral strains, prion strains produce distinguishable disease phenotypes with differing disease onset, duration and clinical signs. Each strain shows also defined biochemical and biological characteristics, varying on the relative susceptibility of the misfolded protein to proteinase digestion, the biochemical signature after digestion, the ability to propagate preferentially in distinct brain regions, the morphology of protein deposits, the extent of neuropathological lesions, or the host range it can infect, which depends on the conformation of the infecting prion strain and its capacity to misfold the PrP^C from the new host (Morales et al., 2007). This latter property, the interspecies transmission ability of prions is, accordingly, limited by the prion strain of the donor and the host's PrP^C amino acid sequence, and results in a transmission barrier that restricts the potential transmissibility to different mammals. However, the barrier can be overcome and prions can adapt to the new host. Despite keeping in some cases features of the original strain, after adaptation to a new host, prions can suffer alterations that provide new biological and biochemical features in the new species (Igel-Egalon et al., 2018). Although this phenomenon is not particularly relevant to this manuscript, it is critical in terms of public health, because the predictability of potential transmission barriers could help prevent new outbreaks in animals and potential zoonoses. On another note, the existence of prion strains as conformational variants or even as complex mixtures of a set of slightly different conformers (Li et al., 2010; Collinge, 2010), is crucial for the diagnosis and detection of prion infections since strain properties determine disease phenotypes, thus, affecting diagnosis based on clinical signs, neuroimaging techniques, surrogate biomarkers or through direct detection of PrP^{Sc} in different brain regions and in tissues or fluids. Moreover, the conformational differences also have an impact on the biochemical features of each strain. For instance it can be difficult immunodetection, as anti-PrP antibodies can specifically recognize some strains while being unable to detect others due to differential proteolytic digestion (Pan et al., 2004). Furthermore, the capacity to detect them through *in vitro* prion propagation can also be affected by the propagation kinetics of strains as some seem to propagate more efficiently than others *in vitro* (Levavasseur et al., 2019).

PrP^C is most abundantly expressed in cells from the nervous system and lymphoreticular system and the toxicity of PrP^{Sc}, although mostly unknown, is mediated by PrP^C on the surface of neurons. For these reasons, the pathology is mainly restricted to the CNS. However, PrP^C is also expressed in other cells and tissues albeit at lower levels (Zomosa-Signoret et al., 2008; Peralta and Eyestone, 2009), and prion propagation in secondary lymphoid organs has also been observed (Mabbott, 2012), meaning that at least some strains have mechanisms for spreading outside of the CNS and are capable of cell-to-cell transmission (Prinz et al., 2002). Thus, the formation or acquisition of minute amounts of PrP^{Sc}, referred as seed, is the initial event of TSE pathogenesis. This seminal event occurs long before the manifestation of the clinical signs of disease, and prions then spread and propagate exponentially in the lymphoreticular system and the nervous system (Gough and Maddison, 2010). In sporadic or hereditary prion diseases, the location of the initial misfolding event is unknown, while in acquired prion diseases ingestion of exogenous PrP^{Sc} is the most common route of infection, after which prions are uptaken by cells from Peyer's patches (Bergstrom et al., 2006). In any case, prions need to reach the CNS from the initial formation or entry site, through cell-to-cell transmission and propagation in peripheral organs such as the secondary lymphoid organs. Those strains for which these processes are more efficient, and are therefore able to reach nervous tissue from peripheral infection sites, are considered to have capacity of neuroinvasion (Nuvolone et al., 2009). In fact, this property increases the transmissibility of certain strains, since poorly neuroinvasive strains would not be able to cause acquired disease (Bett et al., 2012). Conversely, prion strains may also leak from the CNS once the infection is established, causing seeds to reach peripheral tissues and body fluids and in some cases, as for CWD prions of cervids, leading to excretion to the environment (Bosque and Tyler, 2008). In these cases, due to the extraordinary resistance of prions to inactivation by traditional pathogen decontamination procedures or physicochemical treatments, prions can remain in the environment for long periods of time and, initiate infection in a new host upon ingestion (Miller et al., 2004). The difficulties for eliminating or inactivating prions also have important consequences for human prion disease transmission, since iatrogenic cases due to interventions requiring nervous tissue grafting, inadequate decontamination of neurosurgical instruments or injection of cadaveric human growth hormone have been reported (Barrenetxea, 2012).

Bearing all this in mind, early diagnosis of prion diseases, as well as detection of these proteinaceous pathogens in tissues, body fluids and in the environment are critical not only for patients and their relatives, but also to avoid outbreaks which could be

catastrophic for public health and safety due to the potential zoonotic ability of emergent prion strains. Finally, it is also worth noting that other more prevalent protein misfolding-related neurodegenerative disorders in humans, such as synucleinopathies, Alzheimer's disease and other tauopathies, appear to share some molecular mechanisms with prion diseases (Erana et al., 2017). Thus, strategies developed for detection of misfolded proteins or amyloids, could be adapted to the detection of other disease-associated aberrantly folded proteins. In this review, the main methods used in TSE diagnosis and for prion detection will be described with a focus on human prion detection. Common animal TSE detection techniques will also be mentioned as well as the transversal potential of some TSE detection techniques toward other more prevalent neurodegenerative disorders.

Detection of prion infection based on clinical signs and symptoms

Due to their long silent incubation period, the first evidence of prion infections is usually the manifestation of clinical signs and symptoms, which mark the onset of clinical disease. This clinical stage, characterized by a rapidly progressing cognitive and motor decline, invariably leads to the patient's death. As a group of diseases affecting different mammals and given the distinct biochemical and biological properties shown by different strains, TSE present considerably heterogeneous clinical manifestations.

Behavioral changes, ataxia, incoordination, weight loss and overall poor body condition are usual signs found in animals, but many other specific signs for each TSE phenotype have been reported, underlining pruritus in scrapie-affected sheep, poly-uria and polydipsia in CWD-affected deer or gait-abnormalities, aggressive behavior and hyperreactivity to stimuli in BSE-affected cattle among others (Imran and Mahmood, 2011). Human prion diseases, although better clinically characterized, are difficult to diagnose due to their heterogeneity, even among patients from the same family with the same TSE (Chapman et al., 1993; Wadsworth et al., 2006), and also due to the shared clinical signs with other more prevalent neurodegenerative disorders (Geschwind and Murray, 2018). The most common prion disease in humans is the sporadic form of Creutzfeldt-Jakob disease (sCJD), which accounts for around 85% of TSE cases diagnosed in humans (Ladogana et al., 2005). However, several subtypes can be distinguished depending on the biochemical signature of the accumulated PrP^{Sc} in the brain of the patients (type 1 or type 2) and amino acid at position 129 of the host's PrP^C, that can be either a methionine or a valine (MM, MV or VV) and has been shown to modulate disease progression and susceptibility against some prion strains (Parchi and Saverioni, 2012). In agreement with this classification by Parchi and colleagues, the following sCJD subtypes, likely caused by distinct strains, have been described:

- sCJD MM1/VM1, is the most common form by far and it is characterized by early and prominent myoclonus, gait or limb ataxia, myoclonic jerks, visual disturbances (most common in Heidenhain's variant) and an average disease duration of 4 months.
- sCJD VV2, accounting for around 16% of sCJD cases and affecting those homozygous for valine at codon 129, characterized by myoclonus and pyramidal signs, cognitive impairment, late dementia and a little longer disease duration, ranging from 3 to 18 months, although purely ataxic variants at disease onset have been reported, known as the Brownell-Oppenheimer variant.
- sCJD MV2 subtype is the next more prevalent encompassing 10% of the cases and affecting heterozygous individuals, is characterized by ataxia and progressive dementia and the longest average disease duration of about 17 months.
- MM2 is the next most common, affecting homozygous individuals for methionine at codon 129 and manifesting normally with cognitive impairment, aphasia, myoclonus and pyramidal signs, as well as myoclonic jerks.
- VV1, the least prevalent accounting for around 1% of sCJD cases that are normally characterized by the relative youth of the patients at disease onset, personality changes as the initial manifestation and slowly progressive dementia and focal neurologic deficits.

Genetic or hereditary prion diseases are caused by autosomal dominant inheritance of a mutated allele of the PrP encoding gene (*PRNP*). It's penetrance is generally considered high although it may be variable (Minikel et al., 2016). Genetic TSE are classified based on the different disease-associated mutations and the clinical manifestations produced by the misfolded form of PrP^{Sc}, formed due to an increased misfolding proneness of the mutated PrP (Wadsworth et al., 2003). Therefore, upon manifestation of clinical signs compatible with a TSE, genotyping of *PRNP* can confirm the diagnosis in case of familial cases of disease if pathology-associated mutations are found. Among genetic prion diseases, mutations causing phenotypes reminiscent of sporadic CJD are classified as genetic CJD (gCJD), the most common being the E200K mutation. Despite usually showing longer clinical disease duration than sCJD cases, the most frequent clinical signs are indistinguishable from those observed in sCJD and include ataxia, myoclonus, dementia and pyramidal signs, although as in sCJD, high clinical heterogeneity has been reported even between individuals with the same genotype (Ladogana and Kovacs, 2018). Thus, genetic testing is necessary to discriminate between gCJD and sCJD (Schwartz et al., 2019). Besides gCJD, two other genetic prion diseases in humans have been described, Gerstmann-Sträussler-Scheinker syndrome (GSS) and fatal familial insomnia (FFI), which are caused by different mutations in the *PRNP* gene than those already described for gCJD (Wadsworth et al., 2003). GSS was the first genetic prion disease reported, with the most prevalent mutation being P102L (Hsiao et al., 1989). GSS accounts for the most diverse clinical spectrum among prion diseases, usually characterized by prominent cerebellar ataxia accompanied by gradually progressive cognitive decline, although it can also manifest as an isolated cognitive impairment similar to that of Alzheimer's disease. Normally, GSS cases have a slower progress than other TSE, with the longest duration of the clinical phase among human prion disorders and, as will be detailed later, the biochemical signature of the misfolded PrP found in the brains of these patients is also unique among genetic TSE (Liberski and Budka, 2004). The third type of genetic prion disease, FFI is caused by the mutation D178N coupled to methionine at codon 129 of

the mutated allele, whereas the same mutation together with valine at codon 129 results in a form of gCJD, due to the phenotypic manifestation of the disease in each case (Gambetti et al., 2003). Although typical signs of other TSE such as ataxia, myoclonus, gaze abnormalities or cognitive deficits can also be detected in cases of FFI, they are mainly characterized by sleep disturbances due to thalamic deterioration, and early signs of disease include autonomic disturbances such as tachycardia, hyperhidrosis or hypertension (Cracco et al., 2018). Apart from sCJD, two extremely rare sporadic forms of prion disease in humans are also worth mentioning. With an unknown origin and believed to originate due to spontaneous misfolding of the PrP^C in absence of mutations, only a few cases of sporadic fatal insomnia (sFI) and variably protease-sensitive prionopathy (VPSPr) have been described worldwide. The first is indistinguishable from FFI, except for the absence of D178N mutation (Cracco et al., 2018), while VPSPr is phenotypically similar to GSS (Zou et al., 2010).

Finally, despite being practically inexistent nowadays, the clinical features of acquired prion disease in humans will be listed. Variant CJD (vCJD), which arises from ingestion of BSE prions, is infamous for being the only prion zoonosis reported to date (Seed et al., 2018). Around 230 cases have been reported worldwide, the majority of them (~75%) in the United Kingdom, with the last confirmed case published in 2016 (Mok et al., 2017). Barring this last case, which is at present the only clinical case observed in a heterozygous individual for codon 129, all other cases were homozygous for methionine. Among the characteristic clinical features, early psychiatric or sensory symptoms with a delayed onset of neurological abnormalities can be highlighted, with ataxia developing usually later than in other human TSE, and dementia and myoclonus arising subsequently during disease progression. In addition, the affected individuals are in average younger at disease onset than in most TSE, a feature shared with other acquired prion diseases, in which the age at onset does not depend on unknown intrinsic factors but on the age at infection (Brandel and Knight, 2018). The other notorious acquired human TSE is kuru, an already eradicated disease that affected the *fore*, an ethnic group of Papua New Guinea, among which the disease was transmitted due to endocannibalistic rituals. Characterized by cerebellar ataxia, gradual loss of coordination, behavioral changes such as uncontrolled laughter outbursts, and a major prevalence among women and children, its incidence rapidly decayed after the end of cannibalistic rituals (Liberski et al., 2012). Finally, iatrogenic cases of TSEs need to be mentioned, caused by the transmission of sCJD prions via medical procedures such as nervous tissue grafting, neurosurgery with contaminated instruments or injection of cadaveric human growth hormone extracted from pituitary glands of affected individuals (Bonda et al., 2016). Clinical signs in these cases depend on the specific subtype of sCJD from the donor and the genotype of the acceptor and, despite potential variations due to the different infection routes, are overall the same as those reported for sCJD subtypes (Xiao et al., 2014).

In light of the above, it is clear that the clinical heterogeneity of human TSE, together with the similarity of the neurological signs compared with those of other much more prevalent neurodegenerative disorders, prevents definitive diagnosis based on clinical signs. Except for the genetic cases that exhibit the mentioned pathology-associated mutations, for which clinical signs together with genotyping of *PRNP* allows accurate pre-mortem diagnosis, complementary tests are necessary to diagnose the rest of TSE. In fact, definitive diagnosis of TSE was until recently only possible by *post-mortem* histopathological examination of the brain. This is still considered the gold standard, despite recent advances in other prion detection and TSE diagnostic methods (Connor et al., 2019).

Detection of prion infection through electroencephalography and diagnostic imaging

When a TSE is suspected due to clinical signs, several diagnostic imaging techniques as well as electroencephalography (EEG) are used as complementary tests. As early as 1954 (Jones and Nevin, 1954) EEG was reported as an aid to the diagnosis of CJD, and in 1979 a characteristic EEG profile was included among the diagnostic criteria for possible or probable CJD (Masters et al., 1979). Periodic sharp-wave complexes (PSWC) are the most characteristic abnormality in CJD patients, with some studies assigning them specificities ranging from 74% to 86%, sensitivity of 67%, positive predictive value of up to 93% and excellent inter-observer reliability (Steinhoff et al., 2004; Zerr et al., 2000a). However, further retrospective studies showed differences between subtypes, with PSWC being predominant and common for MM1 and MV1 subtypes of sCJD, but not for valine homozygous patients (Zerr et al., 2000b) or vCJD patients (Will et al., 2000). Therefore, although EEG is a relatively inexpensive and sensitive method to assist in the diagnosis of sCJD, it should be interpreted with caution, since it can be normal or show nonspecific abnormalities in the early stages of the disease or in the case of specific disease subtypes (Mundlamurri et al., 2020).

Among bioimaging diagnostic techniques, the use of computerized tomography (CT) was explored in the 80s, but it was ultimately deemed unsuitable since 80% of the patients analyzed had normal scans (Gálvez and Cartier, 1984). Thus, magnetic resonance imaging (MRI) methods, photon emission computed tomography (SPECT) and positron emission tomography (PET) are more commonly applied to TSE diagnosis. Initial studies investigating the use of MRI mostly in sCJD for its considerably higher prevalence compared to the rest of TSE, were performed by analyzing T2 images in a small number of subjects, revealing bilaterally symmetric diffuse hyperintense abnormalities in the basal ganglia on T2-weighted images as a specific sign of sCJD (Barboriak et al., 1994). Additionally, a study with a larger patient cohort showed a 67% sensitivity and 93% specificity, demonstrating the utility of this technique as a detection aid for prion infections (Schroter et al., 2000). In time, diffusion weighted-imaging (DWI) and fluid-attenuated inversion-recovery (FLAIR) were also incorporated into diagnostic practice for the detection of abnormalities related to prion diseases and were even included in the guidelines for sCJD diagnostic from the Centers for Disease Control and Prevention (CDC) in 2010. The most common MRI findings in sCJD patients which can precede the onset of clinical disease, include focal or diffuse, symmetric or asymmetric hyperintensity at the cerebral cortex or basal ganglia (in particular the corpus striatum), or in both regions, with the perirolandic area being usually spared. Cerebellar atrophy is also perceptible and there are

some reports of DWI signal hyperintensity in this region as well, despite it being typically negative when analyzed by imaging. As the disease advances, the extent and degree of signal in subcortical gray matter regions increases in correlation with disease severity (Fragoso et al., 2017). Nonetheless, distinct types and subtypes are characterized by specific MRI findings: MM1/MV1 sCJD subtype show the described findings with frequent basal and cortical involvement while the thalamus is spared; VV1 patients in contrast show prominent cortical involvement with basal ganglia and thalamus spared; and MV2/VV2 types are characterized by predominant involvement of basal ganglia and thalamus with limited cortical affection (Parchi et al., 1999b). Familial CJD cases usually show similar findings to those of sCJD MM1/MV1 types, while for GSS MRI scans are usually normal or may demonstrate diffuse or cerebellum-specific atrophy. In the case of FFI or sFL, conventional MRI tests are usually negative or normal, in line with the limited brain lesions shown by patients at the histopathological level, which makes these patients the most challenging to diagnose based on imaging (Haik et al., 2008). However, few reports with abnormal subcortical patterns or with cortical hyperintensity (in limbic and occipital regions) (Ortega-Cubero et al., 2013), with diffuse abnormal signals in the white matter, basal ganglia and thalamus (Lu et al., 2017), or in which an apparently normal MRI shows an increased apparent diffusion coefficient (ADC) when compared to controls (Haik et al., 2008) have been also published. Determination of the ADC has also yielded promising results for TSE characterized by cerebellar syndrome, which are not detected at nonquantitative DWI (Cohen et al., 2009). Regarding sensitivity, DWI is reported to be better than FLAIR or T2 imaging at least for the detection of cortical abnormalities in sCJD (Shiga et al., 2004; Tschampa et al., 2005), although in the case of vCJD, FLAIR was much more sensitive for the detection of symmetrical hyperintensity in the pulvinar nuclei of the thalamus (pulvinar sign) and the hockey stick sign that characterizes this acquired form of the disease (Collie et al., 2003).

MR spectroscopy has also been applied to the diagnostic of TSE, showing decreased *N*-acetylaspartate:creatinine ratio (NAA:Cr), a marker of neuronal stress and death in sCJD and vCJD patients (Pandya et al., 2003). Increased myoinositol, a marker of astrocytic gliosis, is also detectable in sCJD, vCJD, iatrogenic CJD, genetic CJD and GSS and FFI cases (Galanaud et al., 2010). Moreover, in the case of sCJD, the NAA:Cr ratio has been shown to correlate with disease duration, which makes it a useful parameter for prediction of the clinical course at the early stages (Kim et al., 2011).

Finally, tomographic or functional imaging techniques, such as photon emission computed tomography (SPECT) and positron emission tomography (PET) have also proven their utility for TSE diagnosis. PET with fluorodeoxyglucose ($[^{18}\text{F}]$; FDG-PET) has revealed glucose hypometabolism mainly in cortices of sCJD patients, although alterations in subcortical regions in more advanced stages of the disease have also been reported, even in patients presenting negative CT or MRI scans (Friedland et al., 1984; Ogawa et al., 1995; Henkel et al., 2002; Prieto et al., 2015). On the contrary, the few FFI cases analyzed only presented a slight hypometabolism in the thalamus (Prieto et al., 2015). Comparative studies with previously discussed methods such as EEG and DWI show that FDG-PET can improve diagnostic accuracy when used in combination with other imaging techniques, generally allowing earlier detection and presenting higher sensitivity than DWI (Xing et al., 2012). Changes in regional blood flow in the brain with SPECT using technetium-99m hexamethylpropyleneamine oxime (TC-99m HMPAO) have been reported for some sCJD cases, showing good correlation with findings from other bioimaging techniques or even being detectable before CT or MR abnormalities (Cohen et al., 1989; Kao et al., 1993; Miller et al., 1998). Similar findings have also been reported with another SPECT tracer, *N*-isopropyl-*p*-[123I] iodoamphetamine (123I-IMP), which is considered better than TC-99m HMPAO for the determination of absolute values of regional cerebral blood flow (Matsuda et al., 2001). In any case, SPECT has shown to be a sensitive and useful technique to detect CJD in its early stages and particularly in those cases in which MR is contraindicated (Zhang et al., 2011).

In conclusion, bioimaging techniques are very useful tools for TSE diagnosis, specially when accompanied by TSE's characteristic clinical signs. However, some of the bioimaging techniques are only informative at late disease stages and can have quite low sensitivity or even be unspecific, as similar results can be found for other neurodegenerative disorders. Hence, despite their usefulness, they are normally insufficient to provide a definitive diagnosis of suspected cases, requiring further tests.

Detection of prion infection through measurement of surrogate biomarkers in body fluids

Surrogate biomarkers are indirect indicators of neuronal damage in body fluids that are used to detect prion infection. In this case, instead of looking for macroscopic abnormalities in the brain, as was done with the neuroimaging techniques, molecular biomarkers are sought in body fluids, and normally detected through immunoabsorption or immunoblotting assays. Several proteins, whose levels may be altered due to the neurodegenerative process and which are detectable in cerebrospinal fluid (CSF) or blood, have been proposed as surrogate biomarkers for prion diseases over the years.

The first protein identified as an aid for the diagnosis of CJD in CSF was protein 14-3-3 (Harrington et al., 1986), which is still routinely used for diagnosis of suspected prion disease cases. However, researchers realized early on that it was also increased in patients suffering from other dementias (Hsich et al., 1996; Zerr et al., 2000a). Therefore, increased levels of 14-3-3 in CSF strongly support CJD diagnosis in patients with dementia, but the diagnosis is heavily dependent on the clinical context and additional tests may be required to confirm it, as patients suffering from other neurological diseases with similar clinical manifestations can also present elevated levels of 14-3-3 (Zerr et al., 2000a; Van Everbroeck et al., 2004). Moreover, increased levels of 14-3-3 protein do not occur in all prion disease subtypes. For instance, MV2 and MM2 sCJD subtypes have been reported to show lower sensitivity to this biomarker than other sCJD types, and therefore, its use in combination with other biomarkers has been suggested to improve sensitivity and specificity, increasing the diagnostic accuracy (Sanchez-Juan et al., 2006). Since its description and incorporation into

clinical practice, multicentric and longitudinal studies have been carried out to accurately evaluate its specificity as well as its reproducibility, drawing attention to issues that need to be taken into account. One of these studies highlights the necessity of ring trials or interlaboratory tests to ensure the quality of the analysis and standardize procedures, since different factors such as contamination of CSF with blood can result in false positive signals (Schmitz et al., 2016a). Moreover, specificity strongly depends on the control groups used in different studies, being reduced when patients suffering other neurological pathologies such as Alzheimer's disease (AD), dementia with Lewy bodies (DLB), and vascular dementia (VD) (Van Everbroeck et al., 2004) or acute neuronal injury events and inflammatory and infiltrative neoplastic CNS diseases are included (Stoeck et al., 2012), as all these also show elevated levels of 14-3-3. Thus, even though this biomarker shows overall high sensitivity and is commonly used, being the only surrogate CSF biomarker in current diagnostic criteria for probable CJD, its specificity remains low. For this reason, combination with other assays or biomarkers and even determining relative levels of different 14-3-3 isoforms have all been suggested to improve its diagnostic value (Abu-Rumeileh et al., 2019). It should be noted that all the above mentioned shortcomings could also apply to other surrogate biomarkers in CSF.

Neuron specific enolase (NSE) and S100b proteins were first identified as biomarkers for nervous system damage. Notably, they were also able to indicate whether the damage was neuronal, glial or of mixed origin as well as the extent of the damage (Mokuno et al., 1983; Persson et al., 1987). Both proteins can be found in serum as well as in CSF, allowing for less invasive detection of neurological damage (Persson et al., 1987; Ingebrigtsen et al., 1995; Zerr et al., 1995). Based on these reports they were readily investigated for their applicability to prion disease diagnosis both in CSF (Otto et al., 1997a; Wakayama et al., 1987) and in serum (Otto et al., 1998; Zerr et al., 1995). A comparative study of these two biomarkers with respect to 14-3-3 in CSF of suspected CJD cases showed slightly higher sensitivity for S100b than 14-3-3, which was better than NSE, while in terms of specificity 14-3-3 was superior to the others (Beaudry et al., 1999). Further studies with larger cohorts and including different prion disorders showed similar results for CJD with 14-3-3 showing the highest sensitivity, but also revealed that none of the biomarkers were elevated in GSS or FFI patients. There was however one exception, as S100b was increased in the single GSS case included in the study. When analyzing different sCJD subtypes, sensitivity was again worse for MM2 and MV2 subtypes, making these biomarkers comparable to 14-3-3 in terms of usefulness (Sanchez-Juan et al., 2006). Further comparative studies found strong evidence for elevated concentrations of 14-3-3, S100b and NSE in CSF of sCJD and genetic CJD patients but not in FFI or GSS patients (Ladogana et al., 2009), while detection of different sCJD subtypes showed lower sensitivity for MV2 and MM2 subtypes as previously published, as well as for all heterozygous patients in general (Gmitterova et al., 2016).

Tau and phosphorylated tau protein levels and their relative ratios are also under investigation as biomarkers for the diagnosis of TSE. They have yielded promising results but have yet to be formally accepted as part of a CJD case diagnostic criteria (Zerr et al., 2009). Elevated levels of total tau protein in CSF were evaluated as an indicator of prion disease, based on its utility as a biomarker of Alzheimer's disease in early stages, and the potentially shared pathogenic mechanisms of AD and CJD. Very high levels were found in relation to other dementing disease patients, whose levels were also increased compared to non-demented controls (Otto et al., 1997b). Further studies with larger cohorts and comparing tau with other biomarkers demonstrate an overall better performance of total tau regarding sensitivity and specificity for CJD (Van Everbroeck et al., 2004; Sanchez-Juan et al., 2006; Hamlin et al., 2012; Stoeck et al., 2012; Steinacker et al., 2016). Remarkably, they were also able to discriminate FFI and GSS from controls, despite detecting lower tau levels than for other CJD types (Ladogana et al., 2009). Once more, the presence of other neurodegenerative dementias within the control group was determining for specificity and sensitivity values (Dorey et al., 2015; Abu Rumeileh et al., 2017, 2018). Nevertheless, these values could be greatly improved through measurement and calculation of total tau and phospho-tau ratios, facilitating differential diagnosis with Alzheimer's disease (Riemenschneider et al., 2003; Dorey et al., 2015) or alternatively, measuring and calculating A β peptide: phospho-tau ratios (Lehmann et al., 2019). Despite there being no agreement on total tau cut-off values to support sCJD diagnostic, total tau is a sensitive and specific method for differential diagnosis of CJD and can also serve as a predictor of survival times (Staffaroni et al., 2019), albeit with low specificity for discrimination of CJD from atypical forms of Alzheimer's disease or acute neuronal injuries (Hermann et al., 2021). Nonetheless, the possibility of detecting increases in blood (Thompson et al., 2018; Abu-Rumeileh et al., 2020), its use in combination with other biomarkers or the calculation of total tau and phospho-tau ratios offering better results (Riemenschneider et al., 2003; Dorey et al., 2015) makes it suitable for inclusion among formal diagnostic criteria for CJD diagnosis.

Neurofilament light chain (NfL), a neuron-specific cytoskeleton protein, is also under extensive research as a biomarker for prion diseases, since its presence in body fluids indicates neuroaxonal damage (Petzold, 2005). Detection in CSF has shown very high diagnostic accuracy for sCJD patients with respect to healthy controls, as well as for several genetic CJD cases (Steinacker et al., 2016; Kovacs et al., 2017; Zerr et al., 2018). Moreover, it has been reported as a potential prodromal and prognostic biomarker in plasma (Abu-Rumeileh et al., 2020), although other studies did not find correlation with disease progression (Thompson et al., 2018) or failed to detect any increase in carriers of prion disease-causing mutations prior to disease onset (Vallabh et al., 2019).

Aside from the aforementioned, which can be considered closer to inclusion in official diagnostic criteria with protein 14-3-3 already in use, several other surrogate biomarkers are currently under investigation. In fact, due to the challenging *intra vitam* diagnosis of prion diseases, the search for new molecules that could act as specific indicators of neuronal damage in pre-clinical or early stages of disease is a highly active research area. Among others, decrease in CSF or blood levels of total prion protein (misfolded and native isoforms), as part of a larger panel of biomarkers has shown moderate diagnostic accuracy (Dorey et al., 2015; Abu Rumeileh et al., 2017; Villar-Pique et al., 2019; Llorens et al., 2019). Moreover, it could be potentially used for monitoring the effects of clinical trials, in particular those aimed at reducing native PrP expression levels (Raymond et al., 2019; Vallabh et al., 2019). On the other hand, reduction of A β peptide in CSF of CJD patients has also been observed, which combined

with 14-3-3 protein highly improved sensitivity, specificity, and positive predictive value (Van Everbroeck et al., 2003). This biomarker has also been used in combination with tau and 14-3-3 for the differential diagnosis of CJD and Alzheimer's disease showing promising results (Lehmann et al., 2019). The list of potential biomarkers for prion disease diagnosis is continuously being expanded, including molecules such as malate dehydrogenase 1 (MDH1) (Schmitz et al., 2016b); α , β and γ -synuclein, from which β -synuclein seems the most promising (Oeckl et al., 2016); YKL-40 (also known as chitinase 3-like 1), a marker of neuroinflammation with maximum levels in prion diseases compared to other neurodegenerative disorders (Llorens et al., 2017); neurogranin, also useful for differential diagnosis and reflecting the degree of neuronal damage (Blennow et al., 2019; Vallabh et al., 2020); ubiquitin, already proposed as a biomarker for Alzheimer (Blennow, 2004) which also showed improved diagnostic accuracy for TSE, allowing the discrimination between CJD, AD and FTD patients and healthy controls and importantly, offering better results than previous biomarkers for uncommon sCJD subtypes such as VV2 (Abu-Rumeileh et al., 2020); cell-free mitochondrial DNA (cfmtDNA) in CSF, one of the most recently described, showed increased copy number in CJD compared to other neurodegenerative disorders (Li et al., 2019). Nonetheless, further studies are required to confirm these novel potential biomarkers, mostly due to the small sample size of the preliminary studies but also due to the heterogeneity of prion disease, and its corresponding impact in relative biomarker levels. Moreover, as already stated, ring trials and interlaboratory studies are essential, as well as the establishment of significant cut-off values if they are to be used in routine clinical practice.

Detection of prion infection through direct visualization of PrP^{Sc}, immunohistochemistry, immunoblotting and enzyme-linked immunosorbent assay

The aforementioned diagnostic methods rely on non-specific indicators of neurological damage shared by a number of neurological conditions. In order to offer definitive and unequivocal diagnosis of prionopathies, detection of the pathognomonic marker of disease, PrP^{Sc}, has been the gold standard to confirm diagnostic of TSE for decades. Unfortunately, PrP^{Sc} levels are maximum and detectable mainly in the CNS of affected individuals at late stages of disease, making definitive diagnosis only possible *post-mortem* for a long time (Prusiner, 1987). In fact, identification of histopathological hallmarks, namely vacuolation or spongiform changes, astrocytic gliosis and PrP^{Sc} deposits, in brains of affected patients at necropsy, was considered necessary to confirm clinical diagnosis (Hermann et al., 2021). The detection of PrP^{Sc} in other tissues or body fluids in early stages of disease is usually precluded by the low amounts present in such locations, with notable exceptions such as the presence of prions in lymph nodes, exploited for the detection of animal prion diseases (Grassi, 2003). In order to assess PrP^{Sc} presence in distinct tissues, diverse immunodetection methods have been used, based on different anti-PrP antibodies and proteinase digestion. This allows to distinguish the natively folded isoform (completely sensitive to digestion) from the misfolded, disease-associated PrP^{Sc} (partially resistant to digestion). Immunohistochemistry (IHQ), western blotting (WB) and enzyme-linked immunosorbent (ELISA) assays have been used for that purpose. The first two are more informative in terms of disease subtype identification and classification, since IHQ allows analysis of the PrP^{Sc} deposition pattern and morphology of aggregates and WB permits characterization of the biochemical signature, dependent on the specific disease causing strain. In fact, ELISA, despite its use in research (Pan et al., 2005; Safar et al., 2005; Grassi, 2003), is not commonly applied to clinical diagnosis of human prion diseases. Nevertheless, it is the preferred detection method of prion infections in animals, with several rapid tests based on this assay in the market for the detection of prions in brains (post-mortem, for surveillance and epidemiological purposes) and lymph node biopsies (ante-mortem, for surveillance and outbreak control) from cattle sheep and deer (e.g., TeSeETM sheep/goats ELISA, Bio-Rad, Hercules, CA, United States; PrionicsTM-Check PrioStrip SR, Prionics, Zurich, Switzerland) (Grassi, 2003; Gavie-Widen et al., 2005).

Regarding human prion diseases, histopathological analysis of the brains of affected individuals dates back to the 1950s, when it was applied to the analysis of a familial CJD case in which protein deposits were detected. However, the nature of the protein forming the deposits was still unknown (Jacob et al., 1950; Klatzo et al., 1959). Purification of large amounts of scrapie prions adapted to hamster allowed the identification of the prion protein as constituent of aggregates and boosted production of anti-serum against this protein (Bendheim et al., 1984) paving the way for the development of prion immunodetection methods. These antibodies made it possible to detect PrP^{Sc} in the brains of CJD-affected patients by WB for the first time, confirming the relationship between animal and human TSE and the nature of the protein deposits previously observed by histopathological analysis (Bockman et al., 1985). Since then, IHQ and WB analysis of brain tissue from affected individuals have become routine assays for the diagnosis of TSE, with different disease types showing specific lesion patterns with prominent involvement of certain brain regions, different morphology of protein deposits and distinct biochemical signatures of protease-digested PrP^{Sc}, visualized by WB. In fact, PrP^{Sc} deposition patterns for the different human prionopathies at the final stage of the disease are well characterized and used to distinguish even subtypes or strains, together with the immunoblot analysis (Parchi et al., 1996, 2000; Schoch et al., 2006; Parchi et al., 2009). However, the heterogeneity that characterizes prion diseases also impacts the interpretation of neuropathological profiling as demonstrated by reports of unusual cases (Baiardi et al., 2018). Canonical type 1 sCJD is defined by PrP^{Sc} showing a proteinase K-digested unglycosylated band of ~21 kDa in WB, while type 2 cases present an unglycosylated band corresponding with a protein fragment of ~19 kDa. Polymorphisms at codon 129 modulate histopathological lesion profiles and PrP^{Sc} deposition patterns (Parchi and Saverioni, 2012). MM1 and MV1 subtypes typically show diffuse synaptic type PrP immunostaining mainly in cortical regions and the thalamus, with smaller and variable amounts in the cerebellum, and usually sparing the midbrain and medulla oblongata, and spongiform lesions mainly involving frontal and temporal cerebral cortex with slightly fewer lesions in the cerebellum (Schoch et al., 2006). In contrast, VV1 subtype usually presents faint corticostriatal synaptic

PrP^{Sc} deposition with occasional plaque-like PrP deposits in the gray matter and more spongiform changes in the cerebellum than the frontal cortex. VV2 cases are characterized by perineuronal and the cerebellar plaque-like PrP^{Sc} deposits mainly found in cerebellar granular layer and white matter and by spongiform lesions in subcortical gray matter which are often more severe in the striatum than in the cerebral neocortex. MV2 can be further subdivided in two different phenotypes according to the histopathological analysis. The most common form, known as MV2K (from kuru), shows cerebellar amyloid plaques of the kuru type (unicentric and rounded) mostly in the granular layer with widespread cortical and subcortical pathological changes, whereas the rare MV2C (from cortical) subtype shows large cortical confluent vacuoles and absence of plaque-like PrP^{Sc} deposits. Similarly MM2 subtypes can be further subdivided in cortical (MM2C) and thalamic (MM2T) types, the latter being also defined as the sporadic form of fatal insomnia (sFI) (Kawasaki et al., 1997; Parchi et al., 1999a). MM2C is similar to MV2C form histopathologically, characterized by confluent vacuoles and predominant cortical pathology with perivacuolar PrP^{Sc} staining in cortical layers, while MM2T shows prominent atrophy of thalamic and inferior olivary nuclei with little pathological changes in other areas and minimal PrP^{Sc} deposition. Similar characteristic histopathological features have also been defined for cases presenting mixed phenotypes, and atypical cases that do not fit the pure or mixed subtypes have been also reported, further complicating classification of CJD subtypes (Parchi and Saverioni, 2012). Along this line, histopathological and biochemical analysis of brain tissue is also possible in genetic and acquired forms of prion disease, in some cases allowing distinction between sCJD and other less frequent prionopathies such as vCJD, gCJD, FFI, GSS and VPSPr. For instance, PrP^{Sc} from gCJD, FFI and some specific GSS-associated mutations show similar biochemical signatures to sCJD type 1 and 2 cases, although differences in glycoform ratios (proportion of unglycosylated, monoglycosylated and diglycosylated forms) have been detected (Hill et al., 2006). However, given that patients with the same PrP mutation can show distinct PrP^{Sc} signatures and lesion profiles, combined with the scarcity of cases, the biochemical and histopathological hallmarks of genetic prionopathies are not as precisely defined as those of sCJD cases. GSS cases linked to specific mutations are worth mentioning due to the particular biochemical signature of the PrP^{Sc}, characterized by a ladder-like band pattern with low molecular weight PrP fragments (Kovacs and Budka, 2009). This atypical banding pattern of PrP^{Sc} after digestion has also been observed in the few VPSPr cases reported to date, being considered by some authors as the sporadic form of GSS (Notari et al., 2014). FFI is characterized by predominant spongiform changes and PrP^{Sc} deposits in the thalamus and olivary nucleus, with little or no affection of other brain regions (Budka, 2000). However, in line with the clinical heterogeneity atypical cases have been also described (Sasaki et al., 2005; Shi et al., 2010). Finally, vCJD presents large fibrillary amyloid plaques surrounded by vacuoles, known as florid plaques, many of which are detectable in the cerebral and cerebellar cortices. The biochemical signature of this PrP^{Sc} is similar to that of type 2, showing an unglycosylated band of the same size but different PrP glycoform ratios with the predominant signal corresponding to the diglycosylated PrP (Will et al., 1996; Parchi and Saverioni, 2012). Due to the risk of transmission, vCJD prompted the analysis of PrP^{Sc} presence in other tissues and body fluids, yielding positive results mainly in lymphoid tissue (Hill et al., 1997; Hilton et al., 1998) but also in many others (Wadsworth et al., 2001). This led to the discovery of PrP^{Sc} in a variety of organs, tissues and body fluids in other prionopathies (reviewed in depth in Erana et al., 2020). Detection of PrP^{Sc} in easily accessible tissues and body fluids at early stages of the disease could provide highly specific methods for TSE diagnosis. Prions found in CSF (Erana et al., 2020), blood (Orri et al., 2011; Castilla et al., 2005b), olfactory epithelium (Zanusso et al., 2003; Tabaton et al., 2004) or even skin (Wang et al., 2019) could be key to achieve definitive *intra-vitam* diagnosis. However, the low amounts of PrP^{Sc} in such tissues hinders direct detection by standard immunoassays in most cases. *In vitro* prion propagation techniques, which will be reviewed in the next section, provide the perfect solution to this issue.

Detection of prion infection through indirect observation of PrP^{Sc}, techniques based on *in vitro* prion propagation

As stated previously, immunodetection coupled with protease digestion can be used to determine PrP^{Sc} presence, which can be detected *ante-mortem* directly in certain tissues from some TSE-affected animals (i.e., rectal biopsies in small ruminants and cervids allow direct detection in lymphoid follicles of the rectal mucosa) (Grassi, 2003). However, PrP^{Sc} amounts in peripheral tissues and body fluids are generally too low for direct detection through standard biochemical techniques. This limitation of the use of PrP^{Sc} as a pathognomonic biomarker in human prion diseases has recently been overcome, at least partially, thanks to important advances on cell-free systems for prion propagation, which mimic the PrP^C to PrP^{Sc} conversion observed *in vivo* (Green and Zanusso, 2018). The first cell-free prion propagation system developed required large amounts of PrP^{Sc} (derived from brain homogenates of infected subjects) as seed, purified PrP^C as substrate and showed low conversion yields, limiting its use in diagnosis to the detection of minute amounts of prions (Kocisko et al., 1994). However, since then, *in vitro* prion propagation systems have been further developed, with two emerging as the most effective for the detection of minute PrP^{Sc} amounts, undetectable by direct detection methods. Protein misfolding cyclic amplification (PMCA) came first. This technique substantially improved the misfolding efficiency of the initial method through serial incubation and sonication cycles, allowing the ultrasensitive detection of prions at picogram (pg) levels for the first time coupled to a considerable reduction of the process time (Saborio et al., 2001). This technique can be understood as an analogous of a PCR for amyloids, in which undetectable PrP^{Sc} seeds can be amplified at the expense of PrP^C from the substrate, giving rise to large amounts of *in vitro* produced PrP^{Sc} aggregates, which can be easily detected by protease digestion and WB. Further developments of this method led to an increase in sensitivity through serial PMCA cycles (Castilla et al., 2005b) and addition of beads (Gonzalez-Montalban et al., 2011). Despite being originally conceived to use brain homogenates of infected individuals as seeds, it was readily adapted to detection of PrP^{Sc} in other tissues and body fluids, such as blood, spleen or urine, due to its exceptional potential diagnostic value (Castilla et al., 2005b; Saa et al., 2006; Murayama et al., 2007;

Haley et al., 2009; Chen et al., 2010). PMCA has been used to detect vCJD prions in blood and plasma at pre-clinical stages (Lacroux et al., 2014; Bougard et al., 2016; Concha-Marambio et al., 2016), in urine (Moda et al., 2014) and in CSF (Barria et al., 2018). However, amplification of some sCJD subtypes is more challenging (Bougard et al., 2018), limiting its implementation in the clinical practice. Nonetheless, for other prion diseases such as FFI, promising advances have been made thanks to PMCA, allowing the detection of prions in olfactory mucosa of affected patients (Redaelli et al., 2017). Given that the prions formed *in vitro* by PMCA replicate the main hallmarks of the original seeds including infectivity (Castilla et al., 2005a), strain features (Green et al., 2008) and transmission barrier phenomena (Fernandez-Borges et al., 2009), the method is widely used in TSE research. Nonetheless, its use in clinical diagnosis is limited mainly due to the following reasons: it requires complicated sonication equipment and technical expertise, resulting in inter-laboratory variability; different brain homogenates are needed as substrate depending on the prion strain to be propagated; and the assay requires serial PMCA rounds to achieve maximum sensitivity, as well as a separate readout system based on protease digestion and immunoblotting, which are time consuming and increase the total time needed for diagnosis (Saa and Cervenakova, 2015). Although further developments could improve its diagnostic value, such as the use of recombinant PrP and chemically defined substrates (Wang et al., 2010; Atarashi et al., 2007; Fernández-Borges et al., 2017) to improve consistency, or the use of high-throughput formats and coupled readout methods (Moudjou et al., 2014; Bieschke et al., 2000) which would allow automatization; another cell-free prion propagation system, already established in clinical practice, is preferentially used for diagnosis, the real time Quaking induced conversion (RT-QuIC) (Caughey et al., 2017).

RT-QuIC has revolutionized TSE diagnosis and PrP^{Sc} detection in clinical settings and is being adapted to the detection of other self-replicating misfolded proteins related with different neurodegenerative diseases such as synucleinopathies and tauopathies (Saijo et al., 2019). Since the first report in which this shaking-based recombinant PrP conversion method was shown to detect up to a single infectious particle from prion infected hamster brains and CSF (Atarashi et al., 2008), it has been greatly improved, with an eye on TSE diagnosis. Although the initial version was already faster and technically simpler than PMCA, its wider implementation resulted mainly from two innovations: the adaptation to a multi-well plate format, and the coupling to a readout based on Thioflavin T (ThT) fluorescence (which shows increased fluorescence upon amyloid binding) that can be performed within the same equipment (Wilham et al., 2010; Orru et al., 2012). Additionally, reaction conditions have been fine-tuned to increase process speed and achieve improved sensitivity and specificity, taking detection limits to the range of attograms of PrP^{Sc} in the seed (Orru et al., 2009) and recently, a universal substrate was also described allowing to overcome strain specificity issues (Orru et al., 2015). These changes made the method easily automatable and allowed monitorization of amyloid formation through fluorescence measurements in real time, bringing it closer to routine clinical practice. Despite it has been applied to drug screening and strain identification (Caughey et al., 2017; Candelise et al., 2017), in contrast to PMCA, the aggregates formed during RT-QuIC do not faithfully reproduce the characteristics of the original seeds limiting its applications on research. Nonetheless, due to its desirable features in terms of standardization, reproducibility and ease of use for prion detection in clinical settings, which were confirmed also by ring trials (Cramm et al., 2016; Mcguire et al., 2016), it was included in the diagnostic criteria established by the Centre of Disease Control (CDC) for sCJD in 2018, as well as in European diagnostic criteria used by the UK National CJD Research and Surveillance Unit. Several studies support its use for the detection of prions in CSF of suspected cases of vCJD (Orru et al., 2009), all subtypes of sCJD (Atarashi et al., 2011; Mcguire et al., 2012; Cramm et al., 2015; Foutz et al., 2017), iatrogenic CJD (Villar-Pique et al., 2019) and genetic prion diseases (Sano et al., 2013; Cramm et al., 2015; Foutz et al., 2017), although with lower sensitivity for MM2 subtypes, vCJD, GSS and FFI (Franceschini et al., 2017). Moreover, following immunoprecipitation, vCJD prions have also been detected in blood (Orru et al., 2011); sCJD, gCJD and FFI prions have been found in olfactory epithelium (Orru et al., 2014; Bongianini et al., 2017; Redaelli et al., 2017) and sCJD prions in skin (Orru et al., 2017). Overall, detection of PrP^{Sc} in CSF by RT-QuIC is expected to be the next gold standard for *ante-mortem* diagnosis of TSE. However histopathological analysis and biochemical detection of PrP^{Sc} are still the most widely accepted methods for definitive diagnosis.

Glossary

Anaerobic culture An anaerobic culture means the test is done without letting oxygen get to the sample. Infections caused by anaerobic bacteria can occur almost anywhere in your body. These may be infections in your mouth or lungs, diabetes-related foot infections, infected bites, and gangrene.

Axenic culture A microbial culture that contains only one species, variety, or strain of microorganism. There should not be any contaminants present. Microorganisms that are obligate symbionts, though, cannot be grown in axenic cultures.

CMRL medium CMRL medium was originally developed by Connaught Medical Research Laboratories for the growth of Earle's "L" cells under serum-free conditions. CMRL medium is also especially useful for cloning monkey kidney cells and for growth of many other mammalian cell lines when supplemented with horse or calf serum.

DNase agar DNase agar is a differential medium that tests the ability of an organism to produce an exoenzyme, called deoxyribonuclease or DNase, that hydrolyzes DNA. DNase agar contains nutrients for the bacteria, DNA, and methyl green as an indicator.

RPMI 1640 Medium was originally developed to culture human leukemic cells in suspension and as a monolayer. Roswell Park Memorial Institute (RPMI) 1640 Medium has since been found suitable for a variety of mammalian cells, including HeLa, Jurkat, MCF-7, PC12, PBMC, astrocytes, and carcinomas.

Tryptic soy agar (TSA) Tryptic Soy Agar (TSA) is a non-selective solid medium recommended for use in qualitative procedures for the isolation and cultivation of a wide variety of organisms. Tryptic Soy Agar slants may be used to cultivate, store, and ship bacterial cultures.

Introduction

A microbiological culture, also known as a microbial culture, is a technique for multiplying microorganisms by allowing them to replicate in a predetermined culture medium under carefully regulated laboratory conditions. The word "culture" is more commonly used informally to refer to the laboratory's "selective development" of a particular type of microorganism. Microbial cultures are fundamental and essential diagnostic tools used in microbiology research to assess the type of organism, the concentration of that organism in the sample being studied, or both. It is one of the most popular microbiology diagnostic methods, and is used to determine the cause of infectious disease by allowing the agent to multiply in a predetermined medium. For example, *Streptococcus pyogenes*, the causative agent of strep throat and to identify this bacterium, a throat culture is taken by scraping the lining of tissue in the back of the throat and blotting the sample into a medium to be able to screen the bacteria. The culture conditions could be varied with incubation time, nutrients content, environment, and temperature and thus the condition of culture medium to be fixed by trial and error methods. The birth of culture in clinical microbiology was prompted by microbiologists specializing in intracellular bacteria. The shell vial procedure allowed the culture of new species of *Rickettsia*. The design of axenic media for growing fastidious bacteria like *Tropheryma whippelii* and *Coxiella burnetii* and therefore the ability of amoebal coculture to get new bacteria constituted major advances. Strong efforts combining optimized culture media, detection techniques, and a microaerophilic environment resulted in a drastic reduction in the time it took to culture *Mycobacterium tuberculosis*. The use of a new flexible medium enabled archaea to expand its repertoire.

Finally, the addition of antioxidants to culture media in an aerobic environment permitted the growth of strictly anaerobic bacteria, which improved anaerobe culture in routine bacteriology laboratories. Nevertheless, among usual bacterial pathogens, the event of axenic media for the culture of *Treponema pallidum* or *Mycobacterium leprae* remains an important challenge that the patience and innovations of cultivators will enable them to overcome.

Origin of culture media

Microbiological culture media have their roots in the 19th century, when the study of bacteriology was just getting started. Many bacteriologists have tried, with varying degrees of success, to grow bacteria on the food or material on which the microorganism was first developed. Robert Hooke and Antonie van Leeuwenhoek, two Fellows of the Royal Society, discovered the presence of microscopic species between 1667 and 1676. In 1667, Robert Hooke described the discovery of filamentous fungi, and many years later, Leeuwenhoek discovered and described microscopic protozoa (very small animalcules) known today as *Giardia lamblia* and bacteria while studying various water sources such as rainwater, pond, and well water. On the contrary, fungi and parasite research lagged behind that of other microorganisms and in 1839, fungi were discovered to be the cause of the first human disease, ringworm, which was quickly followed by the discovery of *Candida albicans* as the cause of thrush. It was not until 1910 that Sabouraud introduced a medium that would support the growth of pathogenic fungi. The interest of scientists in studying fungi was often related to crop protection. During the period 1857–78, both Louis Pasteur and Joseph Lister published significant papers on their extensive studies on fermentation.

After microorganisms were visually observed, their growth or reproduction and the idea of spontaneous generation theory created a major controversy and continued for years until 1860. In 1860, Louis Pasteur was the first to use a culture medium for

growing bacteria in the laboratory. This medium consisted of yeast, ash, sugar and ammonium salts. In 1881, Frau Angelina Hesse used his wife's agar (considered an exotic food) as a solidifying agent for bacterial growth.

In 1887, a German microbiologist Julius Richard Petri developed a circular flat dish with a lid called the Petri dish that is used for growing bacteria on a bed of nutrient jelly; this innovation was revolutionized in culture media formulations. With all the research being performed, scientists started to use agar instead of gelatin because it was more resistant to microbial digestion and liquefaction. The Petri dish can be used in any microbiology or immunology laboratory around the world, and its basic architecture has remained unchanged since its inception. Significant advances continued in the 1990s and the use of chromogenic substrates in culture media was shown to improve microbial identification directly from the culture medium. Despite rapid advancements in technology and instrumentation, the basic culture media and ingredients remain most reliable and cost effective tools in microbiology today.

Microorganism growth requirements

As all living organisms, microorganisms also require a combination of various physical and chemical factors for their growth and multiplication. Microbial growth actually refers to increase in numbers of the cells. Cultivation of microorganisms depends on a number of the following important factors.

Physical requirements

Temperature

Bacteria have a minimum, optimum, and maximum temperature for growth and can be divided into four groups based on their growth temperature:

1. Psychrophiles are cold-loving bacteria. Their optimum growth temperature is between -5°C and 15°C . They are usually found in the Arctic and Antarctic regions and in streams fed by glaciers.
2. Mesophiles are bacteria that grow best at moderate temperatures. Their optimum growth temperature is between 25°C and 45°C . Most bacteria are mesophilic and include common soil bacteria and bacteria that live in and on the body.
3. Thermophiles are heat-loving bacteria. Their optimum growth temperature is between 45°C and 70°C and are commonly found in hot springs and in compost heaps.
4. Hyperthermophiles are bacteria that grow at very high temperatures. Their optimum growth temperature is between 70°C and 110°C . They are usually members of the Archaea and are found growing near hydrothermal vents at great depths in the ocean.

Oxygen requirements

Different kinds of bacteria need different amounts of oxygen to survive, which determines which bacteria can infect which parts of the body. Since oxygen is present, they are unable to infect the skin, and they can only expand in the presence of oxygen. Obligate anaerobes, on the other hand, are destroyed by oxygen and carry out fermentation. Tetanus is an obligate anaerobe, which means it can infect areas with little oxygen. Aerotolerant anaerobes breathe anaerobically (without oxygen) but can survive in the presence of oxygen. Bacteria can be classified into one of the following categories based on their oxygen requirements:

1. Obligate aerobes are organisms that grow only in the presence of oxygen. They obtain their energy through aerobic respiration.
2. Microaerophils are organisms that require a low concentration of oxygen (2–10%) for growth, but higher concentrations are inhibitory. They obtain their energy through aerobic respiration.
3. Obligate anaerobes are organisms that grow only in the absence of oxygen and, in fact, are often inhibited or killed in the presence of oxygen. They obtain their energy through anaerobic respiration or fermentation.
4. Aerotolerant anaerobes, like obligate anaerobes, cannot use oxygen to transform energy but can grow in its presence. They obtain energy only by fermentation and are known as obligate fermenters.
5. Facultative anaerobes are organisms that grow with or without oxygen, but generally grow better with oxygen. They obtain their energy through aerobic respiration if oxygen is present, but use fermentation or anaerobic respiration if it is absent. Most bacteria are facultative anaerobes.

pH

Bacteria and other microbes are sensitive to the pH of their surroundings. pH has an effect on large proteins like enzymes. Their shape shifts (they denature), which often results in a shift in the ionic charges on the molecule. In certain cases, the enzymes' catalytic properties are lost, and metabolism is halted. Most bacteria grow best in a pH range of 6.5–7.0, but some thrive in extremely acidic environments and can even withstand pH values as low as 1.0. Acidophiles are bacteria that thrive in acidic environments. Despite the fact that they can survive in extremely acidic conditions, their internal pH is far closer to neutral. Based on their optimum pH requirements, microorganisms can be classified into one of the following groups:

1. Neutrophiles grow best at a pH range of 5–8.
2. Acidophiles grow best at a pH below 5.5.
3. Alkaliphiles grow best at a pH above 8.5.

Some bacteria produce acid as they grow, when this acid is excreted, it decreases the pH of the surrounding environment. This eventually brings bacterial growth to a halt unless something else in the environment neutralizes the bacterial acid. When grown in broth, a buffering agent may be used to mop up excess acid and maintain the pH of the growing culture at optimal levels. Each species of microbe has a specific pH range in which it thrives and reproduces.

Osmosis

Osmotic pressure is of vital importance in biology since the cell membrane is selective against many of the solutes present in living organisms. When a cell is put in a hypertonic solution, water escapes the cell and flows into the surrounding solution, causing the cell to shrink and lose its turgidity. Hypertonic solutions are used for antimicrobial control, on the other hand, salt and sugar are used to create hypertonic environment for microorganisms and are commonly used as food preservatives. Most bacteria require an isotonic environment or a hypotonic environment for optimum growth. Osmotolerant organisms are those that can thrive in relatively high salt concentrations (up to 10%). Halophiles are organisms that need relatively high salt concentrations for development, such as certain archaea that need sodium chloride concentrations of 20% or higher.

Chemical requirements

Microorganisms need a constant supply of chemical nutrients in addition to a suitable physical environment. Microorganisms are often classified based on their energy and carbon sources.

Energy sources

There are two types of bacteria, phototrophic bacteria, such as *Thiocapsa roseopersicina*, which uses light as an energy source by transforming it into an electrochemical gradient of protons (Yurkov and Beatty, 1998), and chemotrophic bacteria, which use the energy of oxidation of mineral or organic compounds as energy sources (Thauer et al., 1977). *Listeria monocytogenes* is found in these bacteria (Van der Horst et al., 2007).

Carbon source

Carbon is the structural backbone of the organic compounds that make up a living cell. Carbon is the most abundant constituent element in bacteria. It is essential for bacteria to produce carbon molecules, such as fats, carbohydrates, proteins and nucleic acids. Bacteria can use inorganic carbon sources, such as carbon dioxide, or organic sources such as sugars and alcohols (Kumar 2012; Atlas, 2010). Based on their source of carbon bacteria can be classified as autotrophs or heterotrophs.

1. *Autotrophs*: require only carbon dioxide as a carbon source. An autotroph can synthesize organic molecules from inorganic nutrients.
2. *Heterotrophs*: require organic forms of carbon. A heterotroph cannot synthesize organic molecules from inorganic nutrients.

Nitrogen source

Nitrogen sources are plentiful, and they can be present in a wide range of compounds used in the formulation of a culture medium. It exists in both organic and inorganic forms, corresponding to protein hydrolysates, especially in the case of hydrolysate, proteose-peptone, or tryptone (Atlas, 2010), and nitrates (Latge 1975). Nitrogen is needed for the synthesis of amino acids, DNA, RNA, and ATP, among other molecules. Depending on the organism, nitrogen, nitrates, ammonia, or organic nitrogen compounds can be used as a nitrogen source.

Minerals sources

Among the common mineral salts, phosphate, sulfate, magnesium or calcium are regularly found. Sulfur is needed for the production of sulfur-containing amino acids and some vitamins. Sulfates, hydrogen sulfide, or sulfur-containing amino acids can be used as a sulfur source, depending on the microorganism type. Phosphate ions are the primary source of phosphorus and phosphorus is needed to synthesize phospholipids, DNA, RNA, and ATP. Potassium, magnesium, and calcium are needed for the function of certain enzymes as well as other functions. Iron is needed in trace amounts by certain enzymes, and trace elements, including potassium, magnesium, calcium, and iron, typically serve as cofactors in enzyme reactions. They include sodium, zinc, copper, molybdenum, manganese, and cobalt ions. During enzyme reactions, cofactors typically serve as electron donors or acceptors.

Water

Water is important for solubilizing nutrients, transporting them, and ensuring that hydrolysis reactions take place. Some bacteria need unrestricted access to water in order to thrive. If evaporation occurs during the incubation of the agar, this water can be lost, resulting in a reduction in colony size and bacterial growth inhibition (Kumar, 2012).

Growth factors

The use of a medium sometimes prevents the growth of bacteria that require unique elements in order to thrive. To improve bacterial multiplication, it's often important to add growth factors to culture media. Growth factors are nutrients that bacteria cannot synthesize from the nutrients available in the environment, such as amino acids, purines, pyrimidines, and vitamins (Kumar 2012; Werkman and Wilson, 1951). Growth factors are needed in small amounts in the culture medium and their requirement is justified by the lack or blockage of a metabolic pathway in the bacterium.

Microbiological media for bacterial growth

Microorganism research is greatly aided by the ability to culture them, or hold reproducing populations alive under laboratory conditions. The first culture media were created through trial and error with environmental components. Overall, the four primary factors that influence bacterial growth are nutrient selection, environment, temperature, and incubation time. Culturing many microorganisms is challenging, because of their extremely specific nutritional and environmental requirements, as well as the diversity of these requirements among different species. A good microbiological culture medium must contain available sources of carbon, nitrogen, inorganic phosphate and sulfur, as well as trace metals, water, vitamins. Originally, these were given in the form of a meat infusion. In culture media, beef or yeast extracts are commonly used instead of meat infusion. Peptones, which are protein digests, are added to provide readily available nitrogen and carbon sources. The medium must have an adequate pH, maintain proper temperature relationships, be free of interfering bioburden, and be free of contamination (Table 1).

Environmental factors in culture media

Atmosphere

The majority of bacteria can grow in normal oxygen tension conditions. Anaerobes expand only in the absence of atmospheric oxygen, while obligatory aerobes need free admission of oxygen. Between these two groups are the microaerophiles, which thrive in partially anaerobic environments, and facultative anaerobes, which may develop in the presence or absence of oxygen. There are several ways to create anaerobic conditions for microorganism growth:

- Addition of small amounts of agar to liquid media.
- Addition of fresh tissue to the medium.
- Addition of a reducing substance to the medium; e.g., sodium thioglycollate, thioglycolic acid and L-cystine.
- Displacement of the air by hydrogen or nitrogen.
- Absorption of the oxygen by chemicals.
- Inoculation into the deep layers of solid media or under a layer of oil in liquid media.

Many microorganisms need a CO₂ concentration of 5–10%. Carbonic acid levels greater than 10% are often inhibitory due to a drop in pH when carbonic acid forms. As culture media are exposed to light and air, their susceptibility to form toxic oxidation products varies.

Table 1 Common Media Constituents and its function.

Constituents	Source	Functions
Water	Primary Drinking Water complying with the U.S. Environmental Protection Agency or comparable regulations of the European Union or Japan.	Purified water is used in the preparation of culture media. Water plays role in solubilizing nutrients, and ensuring hydrolysis reactions
Amino-nitrogen	Peptone, protein hydrolysate, infusions and extracts. Peptones are derived from proteins by hydrolysis or digestion of the source material; e.g., meat, milk.	They are the major sources of nitrogen and vitamins in culture media.
Growth factors	Blood, serum, yeast extractor vitamins, NAD	Needed for fastidious growth of some bacteria.
Energy sources	Sugar, alcohols and carbohydrates	They are used as energy sources as well as a means of distinguishing genera and organisms.
Buffer salts	Phosphates, acetates and citrates	Buffers maintain the pH of culture media.
Mineral salts and metals	Phosphate, sulfate, magnesium, calcium, iron	They usually function as cofactors in enzyme reactions.
Selective agents	Chemicals, antimicrobials and dyes	Selective agents are used in media to inhibit the growth of bacteria, yeasts and fungi.
Indicator dyes	Phenol red, neutral red	Dyes act as bacteriostatic agents or indicators of changes in acidity or alkalinity of the substrate.
Gelling agents	Agar, gelatin, alginate, silica gel	These solidifying agents can be added to a liquid medium in order to change the consistency to a solid or semisolid state.

Water Activity

Proper moisture conditions are necessary for continued growth of microorganisms. Organisms need to be in an aqueous atmosphere of “free” water. The movement of nutrients and toxic waste products requires “free” water, which is not bound in a complex system. During incubation or storage, evaporation causes a loss of “free” water, resulting in a reduction in colony size or complete inhibition of colony growth.

Protective agents and growth factors

Protective agents such as calcium carbonate, soluble starch, and charcoal are used in culture media to neutralize and absorb toxic metabolites formed by bacterial growth. For example, *Haemophilus* species, or *Neisseria* species need the growth factors nicotinamide adenine dinucleotide, NAD (V factor), and hemin (X factor) for enhanced growth. Surfactants, such as polysorbate 80, reduce interfacial tension around bacteria in suspended medium. This behavior allows desired compounds to enter the bacterial cell more quickly, which can boost bacterial growth.

Types of culture media based on the function

The culture media are classified into six types depending on the function: (1) Basal media, (2) Enriched media, (3) Selective media (4) Indicator media, (5) Transport media, and (6) Storage media.

1. *Basal media*. Basal media are those that can be used to grow (culture) bacteria without the need for additional media enrichment. Examples: Nutrient broth, nutrient agar and peptone water.
2. *Enriched media*. Enriched media provides growth factors, vitamins, and other important nutrients to help fastidious organisms develop. These organisms can't make these nutrients and need them to be added to the medium. The media are enriched usually by adding blood, serum or egg. Examples: Enriched media are blood agar and Lowenstein-Jensen media. *Streptococci* grow in blood agar media.
3. *Selective media*. These media favor the growth of a particular bacterium by inhibiting the growth of undesired bacteria and allowing growth of desirable bacteria. Examples: MacConkey agar, Lowenstein-Jensen media, tellurite media (Tellurite inhibits the growth of most of the throat organisms except diphtheria bacilli). Antibiotic may be added to a medium for inhibition.
4. *Indicator (differential) media*. Differential media are bacteriological growth media that contain specific ingredients to allow one to distinguish selected species or categories of bacteria by visual observation. Blood agar is one type of differential medium, allowing bacteria to be distinguished by the type of hemolysis produced. Bismuth sulfite agar uses the ability of bismuth to inhibit most Gram-positive and Gram-negative commensal organisms for the culture of enteric bacilli. An indicator is included in the medium. A particular organism causes change in the indicator, e.g., blood, neutral red, tellurite. Examples: Blood agar and MacConkey agar are indicator media.
5. *Transport media*. Transport media are special media formulated to preserve a specimen and minimize bacterial overgrowth from the time of collection to the time it is received at the laboratory to be processed. Depending on the type of organisms suspected in the sample, transport media may vary. These media are used when species cannot be cultured soon after collection. Examples: Cary-Blair medium, Amies medium, Stuart medium.
6. *Storage media*. Media used for storing the bacteria for a long period of time. Examples: Egg saline medium, chalk cooked meat broth (Table 2).

Quality control of culture media

The importance of a laboratory is determined by the nature of its microbiological media. Many false-negative cultures will result from an enrichment medium that isn't nutritious enough to sustain the target pathogen. A similar situation will arise if a selective medium is too inhibitory, it can kill both the pathogen and the natural flora. However, if the medium is not adequately inhibitory, commensal organisms will overgrow the plate, obscuring the pathogen under investigation. The quality of media can be controlled in two ways: process control and batch control. The latter is sometimes referred to as quality management. Process control depends on having a set of standard operating procedures for operation of equipment used in media production, sterilization, methods and recipes describing the production of medium whether this be from a commercial manufacturer or made up in-house. The consistency of the reagents that go into the medium, including the pH and ion content of the water, must also be clearly defined and methods for measurement and if necessary rejection of batches laid down. Two aspects of batch control must be considered: the medium's physical characteristics and its microbiological efficiency.

Physical characteristics

The tests undertaken for the physical characteristics of culture media vary depending upon the type of media. Examples of physical tests include:

- *Visual test for color*: The color of a sterilized medium should be compared to a non-sterilized medium and any differences in color to be noted.
- *Visual test for clarity*: The clarity of the media should be examined for optical artefacts, such as crystallization.

Table 2 Common microbiological media in routine use.

Nutrient Broth	This medium is used as a basal media for the preparation of other media and to study soluble products of bacteria. It contains 500 g meat, e.g., ox heart is minced and mixed with 1 L water. 10 g peptone and 5 g sodium chloride are added, pH is adjusted to 7.3.
Nutrient Agar	Nutrient agar is a general purpose medium used to support for the growth of a wide range of non-fastidious bacteria. It is solid at 37 °C. Usually 2.5% agar is added in nutrient broth and then heated at 100 °C to melt the agar and then cooled.
Peptone Water	Peptone 1.0% and sodium chloride 0.5%. It is used as base for sugar media and to test indole formation.
Blood Agar	Most commonly used medium. 5–10% defibrinated sheep or horse blood is added to melted agar at 45–50 °C. Blood acts as an enrichment material and also as an indicator. Certain bacteria when grown in blood agar produce hemolysis around their colonies. Certain bacteria produce no hemolysis. The colony is surrounded by a clear zone of complete hemolysis, e.g., <i>Streptococcus pyogenes</i> is a β -hemolytic streptococci, or α -hemolysis. The colony is surrounded by a zone of greenish discoloration due to formation of biliverdin, e.g., <i>Streptococci, viridans</i> Gamma γ -hemolysis, or, No hemolysis. There is no change in the medium surrounding the colony.
Chocolate Agar or Heated Blood agar	Prepared by heating blood agar and is used for culture of <i>Pneumococcus, Gonococcus, Meningococcus</i> and <i>Haemophilus</i> . Heating the blood inactivates inhibitor of growths.
MacConkey Agar	It is a selective and indicator medium for enterobacteriaceae, which contains agar, peptone, sodium chloride, bile salt, lactose and neutral red. Selective as bile salt does not inhibit the growth of enterobacteriaceae but inhibits growth of many other bacteria. Indicator medium as the colonies of bacteria that ferment lactose take a pink color due to production of acid. Acid turns the indicator neutral red to pink. These bacteria are called 'lactose fermenter', e.g., <i>Escherichia coli</i> . Colorless colony indicates that lactose is not fermented, i.e., the bacterium is non-lactose fermenter, e.g., <i>Salmonella, Shigella, Vibrio</i> spp.
Mueller Hinton Agar	Disc diffusion sensitivity tests for antimicrobial drugs should be carried out on this media as per WHO recommendation to promote reproducibility and comparability of results.
Hiss's Serum Water Medium	This medium is used to study the fermentation reactions of bacteria which cannot grow in peptone water sugar media, e.g., <i>Pneumococcus, Neisseria</i> , and <i>Corynebacterium</i> spp.
Lowenstein-Jensen Medium	The Löwenstein-Jensen medium, more commonly known as LJ medium, is a growth medium specially for <i>Mycobacterium</i> species, notably <i>Mycobacterium tuberculosis</i> . It contains egg, malachite green and glycerol. Egg is an enrichment material which stimulates the growth of tubercle bacilli, malachite green inhibits growth of organisms other than <i>Mycobacteria</i> , glycerol promotes the growth of <i>Mycobacterium tuberculosis</i> but not <i>Mycobacterium bovis</i> .
Dubos Medium	This liquid medium is used for <i>tubercle bacilli</i> . It contains "tween 80," bovine serum albumin, casein hydrolysate, asparagine and salts. Tween 80 causes dispersed growth and bovine albumin causes rapid growth.
Loeffler Serum Medium	This medium is used for <i>Corynebacterium</i> culture, which contains coagulated serum of sheep, ox or horse for enrichment. <i>Corynebacterium Diphtheria</i> grow in this medium in 6 h while the secondary bacteria do not grow. It is used for rapid diagnosis of diphtheria and to demonstrate volutin granules, sometimes termed metachromatic granules because of their color reaction with the dyes used in light microscopy.
Tellurite Blood Agar	It is used as a selective medium for isolation of <i>Corynebacterium diphtheria</i> . It is selective due to the presence of inhibitor and differential by means of ability of organism to reduce potassium tellurite.
Stuart Transport Medium	Stuart Transport Medium is a non-nutritional medium which maintains the viability of organisms without significant multiplication. The small agar content provides a semisolid consistency which prevents oxidation and drying during transport.
Thiosulfate-citrate-bile salts-sucrose (TCBS)	TCBS Agar is used for the selective isolation of <i>Vibrio</i> spp. from a variety of clinical and nonclinical specimens. This medium has a very high pH (8.5–9.5) which suppresses growth of intestinal flora other than <i>Vibrio</i> spp. <i>V. cholerae</i> is yellow on this medium, <i>V. parahaemolyticus</i> is green on this medium.
Selenite F broth	Selenite-F Broth is used as an enrichment medium for the isolation of <i>Salmonella</i> spp. from feces, urine, water, foods and other materials of sanitary importance. The casein peptone provides essential nitrogenous and carbon compounds. The lactose in the medium serves to maintain a uniform pH.

- **Gel strength:** The gel strength should not be over-hard or over-soft, but firm and usable.
- **pH of the finished media:** This is possibly the most critical chemical test, because if the pH is outside of the recommended range for the media, some of the microorganisms that the media is designed to develop will be inhibited.
- **Checks for damage:** Plates and bottles should be examined for damage like cracks and defects.

Microbiological characteristics

1. **Sterility test:** The test of media sterility is designed to detect microbial contamination during the manufacturing process. Here a small number, normally 2% of the batch, of uninoculated items are incubated. The temperature and time selected for the sterility test incubation will depend upon the type of media. For general-purpose media, a temperature of 30–35 °C for 3 days is typical. To pass the sterility test the items must demonstrate no growth.
2. **Growth performance test:** The microbial growth performance of media should be controlled with a panel of standard organisms. These may be established locally but it is better to use those recommended in standard textbooks, by the PHLS or by the American NCCLS. Stocks of control organisms can be obtained from the National Collection of Type Cultures and American Type Culture Collection.

Table 3 Examples of control organisms for quality control of laboratory medium.

Quality control strain	Culture medium	Expected output
<i>Strep. pyogenes</i> ATCC 19615	Blood agar	Small clear gray beta-hemolytic colonies
<i>Streptococcus pneumoniae</i>	Blood agar	Alpha hemolytic, small greenish colonies
<i>Escherichia coli</i> (ATCC® 25,922™)	MacConkey agar	Lactose fermenting pink colonies
<i>Acinetobacter baumannii</i> (ATCC® 19,606™)	MacConkey agar	Non-Lactose fermenting pale colonies
<i>Shigella sonnei</i> (ATCC® 25,931™)	XLD agar	Red pink colonies
<i>Salmonella enterica</i> subsp. <i>enterica</i> (ATCC® 14,028™)	XLD agar	Red pink colonies with black center
<i>Legionella pneumophila</i>	Buffered charcoal yeast extract (BCYE) agar	Black centered gray colonies
<i>Enterococcus faecalis</i> (ATCC® 29,212™)	Bile esculin agar	Small transparent colonies with brown-black halos.
<i>N. gonorrhoeae</i> NCTC 8375	Thayer martin agar	Water droplet like colonies
<i>Staphylococcus aureus</i> (ATCC® 25,923™)	Mannitol Salt agar	Golden Yellow colonies
<i>Escherichia coli</i> (ATCC® 25,922™)	EMB agar	Blue-black bull's eye like colonies with green metallic sheen

Standard cultures are used to ensure that medium is sufficiently nutritious to support the growth of fastidious pathogens. This may be achieved by performing a viable count of an overnight growth of a control organism or by the Miles and Misra technique or counting the colonies after a standardized plating method. In addition to demonstrating adequate nutritional support characteristic appearances or responses, such as beta-hemolysis or colored colonies due to indicator changes, should be present. The ability to kill undesirable species should be demonstrated alongside support for the target organisms in selective media. Some examples of control organisms are given in Table 3.

Aseptic technique, dilution, streaking, and spread plates

In microbiology, several techniques including aseptic technique, dilution, colony streaking and spread plates are used in day-to-day experiments. Microbiologists have many tools, but they use four relatively basic techniques on a daily basis, which are illustrated here.

- Aseptic technique* or sterile technique is used to avoid contamination of sterile media and equipment during bacterial cell culture. Sterile technique should always be employed when working with live cell cultures and reagents/media that will be used for such cultures. This technique involves using flame to kill contaminating organisms, and a general mode of operation that minimizes exposure of sterile media and equipment to contaminants. When working with cultures of living organisms, it is extremely important to maintain the environments in which cells are cultured and manipulated as free of other organisms as possible. This necessitates limiting the exposure of sterilized culture media containers to outside air and using a flame to “re-sterilize” container lids and rims. This entails passing rims and lids through a Bunsen burner’s flame to destroy microorganisms that come into contact with those surfaces.
- Serial dilution*: Serial dilution is the method of diluting a sample with a sterile diluent, which can be either distilled water or 0.9% saline, in a sequence of standard volumes. Then, using a small measured volume of each dilution, a series of pour or spread plates are formed. The degree of dilution is calculated based on the approximate concentration of cells/organisms in a sample. For example, if a water sample is taken from an extremely polluted environment, the dilution factor is increased. In contrast, for a less contaminated sample, a low dilution factor might be sufficient (Fig. 1).

Serial twofold and tenfold dilutions are commonly used to titer antibodies or prepare diluted analytes in the laboratory. The dilution factor in a serial dilution can be determined either for an individual test tube or can be calculated as a total dilution factor in the entire series.

The dilution factor of each tube in a set:

$$\frac{\text{Volume of Sample}}{\text{Volume of Sample} + \text{Volume of diluent}}$$

For a 10-fold dilution, 1 mL of sample is added to 9 mL of diluent. In this case, the dilution factor for that test tube will be:

$$\text{Dilution factor formula} = \frac{1 \text{ mL}}{1 \text{ mL} + 9 \text{ mL}} = 1/10 = 10^{-1}$$

After the first tube, each tube is the dilution of the previous dilution tube.

Now, for total dilution factor,

Fig. 1 A ten-fold serial dilution, which can also be called a 1:10 dilution, or a series with dilution factor of 10.

Total dilution factor for the second tube = dilution of first tube $\times$ dilution of the second tube.

Example:

For the first tube, dilution factor = 10^{-1} (1 mL added to 9 mL).

For the second tube, dilution factor = 10^{-1} (1 mL added to 9 mL).

$$\begin{aligned} \text{Total dilution factor} &= \text{previous dilution} \times \text{dilution of next tube} \\ &= \text{total dilution of } 10^{-1} \times 10^{-1} = 10^{-2} \end{aligned}$$

Serial dilution is used in microbiology to estimate the concentration or number of cells/organisms in a sample to obtain an incubated plate with an easily countable number of colonies.

c) **Streak plate:** In microbiology, streaking is a technique used to isolate a pure strain from a single species of microorganism, often bacteria. Streak plate technique is used for the isolation of a pure culture of the organisms (mostly bacteria), from a mixed population. The inoculum is streaked over the agar surface in such a way that it “thins out” the bacteria. Some individual bacterial cells are separated and well-spaced from each other. Usually, by the third or fourth quadrant, only a few organisms are transferred which will give discrete colony forming units (CFUs). Samples can then be taken from the resulting colonies and a microbiological culture can be grown on a new plate so that the organism can be identified, studied, or tested. The streaking is done using a sterile tool, such as a cotton swab or commonly an inoculation loop. This is dipped in an inoculum such as a broth or patient specimen containing many species of bacteria. The sample is spread across one quadrant of a petri dish containing a growth medium, usually an agar plate which has been sterilized in an autoclave. Choice of which growth medium is used depends on which microorganism is being cultured, or selected for. Growth media are usually forms of agar, a gelatinous substance derived from seaweed (Fig. 2).

Procedure for streaking a plate for isolation:

1. Flame the loop and wire and *streak* a loopful of broth as at A in the diagram.
 2. Reflame the loop and cool it.
 3. Streak as at B to spread the original inoculum over more of the agar.
 4. Reflame the loop and cool it.
 5. Streak as at C.
 6. Reflame the loop and cool it.
 7. Streak as at D.
- d) **Spread plate:** The spread plate technique involves using a sterilized spreader with a smooth surface made of metal or glass to apply a small amount of bacteria suspended in a solution over a plate. The plate needs to be dry and at room temperature so that the agar can absorb the bacteria more readily. No subsurface colonies appear in spread plate so isolation of the organism is easy. Volume no greater than 0.1 mL can be spread on the nutrient agar plate because it would not soaked well and may result colonies to form coalesce.

Fig. 2 Streaking procedure.

A perfect spread plate technique will result in visible and isolated colonies of bacteria that are evenly distributed in the plate and are countable as shown in the above figure.

- e) *Special Culture Techniques*: Many microbes have special growth conditions or require precautions to grow in a laboratory setting, leading to special culture techniques. A microaerophile is a microorganism that requires oxygen to survive, but requires environments containing lower levels of oxygen than are present in the atmosphere (~20% concentration). In the laboratory they can be easily cultivated in a candle jar. A candle jar is a container into which a lit candle is introduced before sealing the container's airtight lid. The candle's flame burns until extinguished by oxygen deprivation, which creates a carbon dioxide-rich, oxygen-poor atmosphere in the jar. Many labs also have access directly to carbon dioxide and can add the desired carbon dioxide levels directly to incubators where they want to grow microaerophiles (Fig. 3).

Fig. 3 Candle jar: A candle is lit in a jar with a culture plate. The lid is put on, as the candle burns it increases the carbon dioxide levels in the jar. Adopted from Special Culture Techniques. From <https://bio.libretexts.org/@go/page/9166>.

Nottingham and Hungate first used a nonselective medium but a stringent atmosphere consisting of 80% H₂ and 20% CO₂ to isolate nonidentified methanogenic Archaea from humans (Nottingham and Hungate, 1968). When the concentration of oxygen required to obtain growth is relatively low, the bacterial species are considered microaerophiles, such as *Campylobacter* spp., which can cause human infections involving primarily the gastrointestinal tract (Fitzgerald and Nachamkin, 2007). Most *Campylobacter* species require a microaerobic atmosphere containing 5% O₂, 10% CO₂, and 85% N₂ for optimal recovery. Recently, a microaerophilic atmosphere demonstrated better efficiency than aerobic conditions in promoting *Mycobacterium* culture and was proposed as a routine condition for laboratories performing these cultures (Chodbane et al., 2014).

To date spirochaetes are very difficult to rear in a controlled laboratory environment. This also includes other human pathogens like the bacterium that causes Lyme disease. Using animals to culture human-pathogens has problems. First, the use of animals is always difficult for technical and ethical reasons. Also, a microbe growing on animal other than a human may behave very differently from how that same microbe will behave on a human. Some human pathogens are grown directly on cells cultured from humans. Exemplified by the bacteria *Chlamydia trachomatis*, the bacteria responsible for the sexually transmitted infection (STI) in humans known as Chlamydia. As *Chlamydia trachomatis* only grows in humans. The human cell culture known as McCoy cell culture is used to culture this bacteria (Fig. 4).

Fig. 4 Chlamydia bacteria group. Light microscope view of cells infected with chlamydia as shown by the brown inclusion bodies. Adopted from Special Culture Techniques. from <https://bio.libretexts.org/@go/page/9166>.

Aseptic culture transfer technique

Microorganisms are transferred from one medium to another by subculturing. This technique is of basic importance and is used routinely in preparing and maintaining stock cultures, as well as in microbiological test procedures. The essential steps involved in aseptic transfer of microorganisms are as follows:

1. An inoculating loop is sterilized by holding it in the hottest portion of the Bunsen burner flame until the entire wire becomes red-hot. Once flamed, the loop is held in the hand and allowed to cool for 10–20 s.
2. The cotton plug of the stock culture tube is unplugged with the help of little finger, the neck of the tube is briefly passed through the flame and the sterile loop is further cooled by touching it to the sterile wall of the culture tube before removing a small sample of inoculum.
3. The neck of the stock culture tube is flamed and the cotton plug is reinserted.
4. The cotton plug of the subculture tube is unplugged likewise, the neck of the tube is briefly passed through the flame and the cell-laden loop is inserted into the subculture tube.
5. In case of a broth medium, the loop is shaken slightly to dislodge the organisms; with an agar slant medium, it is drawn lightly over the hardened surface in a zigzag line.
6. The neck of the subculture tube is flamed and the cotton plug is reinserted.
7. Following inoculation, the loop is again flamed to destroy remaining organisms.
8. In case of liquid-liquid transfer, sterile tips are used to inoculate cultures (1%) (Fig. 5).

Culture transfer procedure. Adapted from <http://microbiologist161998.blogspot.com/2017/09/the-first-experiment.html>.

Pure culture

A pure culture is a population of cells or multicellular organisms growing in the absence of other species or types. A pure cultures can be grown in petri dishes of differing sizes that have a thin layer of agar-based growth medium. Once the growth medium in the petri dish is inoculated with the desired bacteria, the plates are incubated at the best temperature for the growing of the selected bacteria (for example, usually at 37 °C for cultures from humans or animals or lower for environmental cultures). Another method of bacterial culture is liquid culture, in which the desired bacteria are suspended in liquid broth, a nutrient medium. These are ideal for

Fig. 5 Culture transfer procedure. Adapted from <http://microbiologist161998.blogspot.com/2017/09/the-first-experiment.html>.

preparation of an antimicrobial assay. The experimenter would inoculate liquid broth with bacteria and let it grow overnight (they may use a shaker for uniform growth). Then they would take aliquots of the sample to test for the antimicrobial activity of a specific drug or protein (antimicrobial peptides). As an alternative, the microbiologist may decide to use static liquid cultures. These cultures are not shaken and they provide the microbes with an oxygen gradient.

Isolation of pure culture

Microorganisms exist in nature as mixed populations and to study microorganisms in the laboratory, we must have them in the form of a pure culture, that is, one in which all organisms are descendants of the same organism. Two major steps are involved in obtaining pure cultures from a mixed population:

1. The mixture must be diluted until the various individual microorganisms become separated far enough apart on an agar surface that after incubation they form visible colonies isolated from the colonies of other microorganisms. This plate is called an isolation plate.
2. Then, an isolated colony can be aseptically “picked off” the isolation plate (Fig. 6) and transferred to new sterile medium. After incubation, all organisms in the new culture will be descendants of the same organism, that is, a pure culture.

Fig. 6 Picking a single colony from a Petri Plate in order to obtain a pure culture. Before removing bacteria from the petri plate, first cool the loop by sticking it into the agar away from any growth. Adopted from Pure Cultures from a Mixed Population. from <https://bio.libretexts.org/@go/page/3442>.

Enrichment & isolation

Enrichment culture is the technique that is used to enhance the population density of a particular group of microorganisms within the total microbial population of a sample. This is achieved by preferentially stimulating the growth of the target group of microorganisms by judicious manipulation of the physiological conditions during the enrichment phase. Enriched media contain the nutrients required to support the growth of a wide variety of organisms, including some of the more fastidious ones. They are commonly used to harvest as many different types of microbes as are present in the specimen. Enrichment culture is the use of certain growth media to favor the growth of a particular microorganism over others, enriching a sample for the microorganism of interest. Enrichment cultures are used to increase a small number of desired organisms to detectable levels. For example, the primary enrichment component is blood, which provides hemin and other nutrients. This component is frequently added to agar media in several commercial media to notably increase the growth of anaerobic bacterial species (Sonnenwirth, 1972). Blood agar, which was initially accidentally used for *Mycobacterium tuberculosis* culture, was also shown to be a cost- and time-effective method, with better growth than with the egg-based agar reference medium (Drancourt et al., 2003; Drancourt and Raoult, 2007).

In addition, sometimes the number of pathogens present in biological samples are lower than the detection limits of the available methods, thus requiring additional pre-enrichment steps which add costs to the diagnostics and increase the turnaround time. Moreover, samples usually associated with low bacterial numbers (e.g., CNS fluid) or in mixed populations (e.g., stool), can benefit from a diagnostic approach using enrichment of samples prior to downstream processing (Sande et al. 2020). Broth enrichment media are used when high sensitivity is required e.g. for detection of bacteria from CSF, or to detect small numbers of *Salmonella* in a stool sample containing many millions of other bacteria.

Enumeration of bacteria

To determine rates of microbial growth and death, it is necessary to enumerate microorganisms, that is, to determine their numbers. It is also often essential to determine the number of microorganisms in a given sample. For example, the ability to determine the safety of many foods and drugs depends on knowing the levels of microorganisms in those products. A variety of methods has been developed for the enumeration of microbes and these methods measure cell numbers, cell mass, or cell constituents that are proportional to cell number. The four general approaches used for estimating the sizes of microbial populations are direct and indirect counts of cells and direct and indirect measurements of microbial biomass. Each method will be described in more detail below.

Direct count of cells

Cells are counted directly under the microscope or by an electronic particle counter. Two of the most common procedures used in microbiology are discussed below.

Direct count using a counting chamber

Direct microscopic counts are performed by spreading a measured volume of sample over a known area of a slide, counting representative microscopic fields, and relating the averages back to the appropriate volume-area factors. Specially constructed

Fig. 7 An example of counting colonies on a streak plate. Adopted from Direct counting of Bacteria. From <https://courses.lumenlearning.com/boundless-microbiology/chapter/counting-bacteria/>.

counting chambers, such as the Petroff-Hauser and Levy counting chambers, simplify the direct counting procedure because they are made with depressions in which a known volume overlies an area that is ruled into squares. The ability to count a defined area and convert the numbers observed directly to volume makes the direct enumeration procedure relatively easy. Direct counting procedures are rapid but have the disadvantage that they do not discriminate between living and dead cells. This method is used to assess the sanitation level of a food product and in performing blood cell counts in hematology. The differential white blood cell count, which is used as an indication of the nature of a microbial infection, involves direct counting of blood cells that have been stained to differentiate different types of white blood cells (Fig. 7).

Direct count using fluorescent dyes

Fluorescent dyes are becoming more used in recent years for a variety of procedures, one of which is bacterial counts. These dyes can be employed to stain all species, a particular species of interest in an environmental sample or even a specific component of cells. The most widely used fluorescent dye for counting the number of bacterial cells is acridine orange which stains both living and dead cells by interacting with DNA and protein components of cells. The stained cells fluoresce orange when excited near ultraviolet light. This stain is particularly useful for determining the total number of microorganisms in samples, such as soil and water, where the co-existence of metabolically diverse populations precludes establishing conditions for the simultaneous enumeration of microbial populations by viable count procedures. The procedure is widely used where population levels are often low and where viable plate counts are known to severely underestimate total number of bacteria. Typically, the viable count is less than 1% of the direct count for marine samples. In this procedure the bacteria in a known volume of sample are stained with acridine orange and the sample is then filtered through a 0.22 μm filter. The bacteria are trapped on the filter that is then examined under a fluorescence microscope. The bacteria in a defined area of the filter are counted and the concentration in the original sample is then calculated. Other fluorescent dyes that are also gaining popularity are cyanoditolyl tetrazolium chloride (CTC), auramine and rhodamine. CTC binds to respiration proteins in the cell and thus can demonstrate live cells. Auramine and rhodamine bind to cell wall of Mycobacteria and emit bright yellow or orange color under a fluorescent microscope. These latter stains are gradually replacing the acid-fast stain.

Indirect count of cells

Microorganisms in a sample are diluted or concentrated and grown on a suitable medium; the development of growing microorganisms (for example, colony formation on agar plates) is then used to estimate the numbers of microorganisms in the original sample.

Viable cell counting

Plate counting is used to estimate the number of viable cells that are present in a sample. A viable cell count allows one to identify the number of actively growing/dividing cells in a sample. The plate count method or spread plate relies on bacteria growing a colony on a nutrient medium. The colony becomes visible to the naked eye and the number of colonies on a plate can be counted. The most common procedure for the enumeration of bacteria is the viable plate count. In this method, serial dilutions of a sample containing viable microorganisms are plated onto a suitable growth medium. The suspension is either spread onto the surface of agar plates (spread plate method), or is mixed with molten agar, poured into plates, and allowed to solidify (pour plate method). The plates are then incubated under conditions that permit microbial reproduction so that colonies develop that can be seen without the aid of a microscope. It is assumed that each bacterial colony arises from an individual cell that has undergone cell division. Therefore, by counting the number of colonies and accounting for the dilution factor, the number of bacteria in the original sample can be determined (Fig. 8).

Fig. 8 An example of viable bacterial colonies count.

There are several drawbacks to the viable count method. The major disadvantage is that it is selective and therefore biased. The nature of the growth conditions, including the composition and pH of the medium used as well as the conditions such as temperature, determines which bacteria in a mixed population can grow. Since there is no universal set of conditions that permits the growth of all microorganisms, it is impossible to enumerate all microorganisms by viable plating. This same disadvantage, however, becomes advantageous when one is interested in only a specific microbial population. For example, we can design selective procedures for the enumeration of coliforms and other physiologically defined microbial groups. The viable count is an estimate of the number of cells. Because some organisms exist as pairs or groups and because mixing and shaking of the sample does not always separate all the cells, we actually get a count of the “colony forming units.” One cell or group of cells will produce one colony, therefore when we record results for a viable count, it is customary to record the results as colony forming units per ml (cfu/mL) or per gram (cfu/g) of test material.

Because we generally have no idea of how many bacteria are in a sample, it is almost always necessary to prepare a dilution series to ensure that we obtain a dilution containing a reasonable number of bacteria to count. Dilutions in the range 10^{-1} (1/10) to 10^{-8} (1/100,000,000) are generally used, although with particular types of samples the range of dilutions can be restricted. For example, for water that is not turbid, the maximal dilution needed is 10^{-6} because we know that if there were 10^7 or more bacteria per milliliter, the water would be turbid.

The most probable number (MPN)

The most probable number procedure dates back to the earliest days of microbiology. However, it is still widely used in sanitary bacteriology to estimate numbers of coliforms in water, milk, and other foods. Coliforms are bacteria that reside in the intestine of warm-blooded mammals and are regularly excreted in the feces. They are Gram negative rods belonging to the Enterobacteriaceae family, ferment lactose and produce gas. Not all members of Enterobacteriaceae are coliforms.

The MPN procedure is a statistical method based upon the probability theory. Samples are serially diluted to the point of extinction, that is, to a point where there are no more viable microorganisms. To detect the end point, multiple serial dilutions are inoculated into a suitable growth medium, and the development of some recognizable characteristic, such as acid production or turbidity, is used to indicate growth (the presence of at least one viable microorganism in the diluted sample). The pattern of positive tests (growth) in the replicates and statistical probability tables are used to determine the concentration (most probable number) of bacteria in the original sample. Statistical MPN tables are available for replicates of 3, 5, and 10 tubes of each dilution. The more replicate tubes used, the greater the precision of the estimate of the size of the bacterial population.

For example, a three-tube MPN procedure to estimate the numbers of coliforms in a water sample as shown in Fig. 9. First, decimal dilutions of the sample are prepared and then 1 mL of each dilution is inoculated into three broth culture tubes (different numbers of replicates and dilution series can be used). After incubation, tubes are examined for turbidity and those that are positive are recorded for each dilution. For example, if all tubes show growth, the results will be noted as 333. Once the results have been noted, the MPN table (MacGrady table) should be used to determine the most probable number of microorganisms for mL or g.

Direct measurement of microbial biomass

Cell mass is determined directly by weighing whole cells; biomass can be correlated with cell numbers by reference to a standard curve. Wet weight or dry weight of bacteria may be used for estimation of cell numbers.

Fig. 9 The enumeration of coliforms in water using the Most Probable Number (MPN) method APHA/AWWA/WEF 2005 (Hunt and Rice, 2005).

Indirect measurement of microbial biomass

Microbial biomass is estimated by measuring relatively constant biochemical components of microbial cells, such as protein, ATP, lipopolysaccharides, peptidoglycan, and chlorophyll; biomass can also be indirectly estimated by measured turbidity that can then be correlated with cell numbers by reference to a standard curve. Various procedures based on the detection of specific microbial macromolecules or metabolic products can be used to estimate numbers of microorganisms. For example, peptidoglycan can be quantified, and because this biochemical occurs exclusively in the cell wall of bacteria, the concentration of peptidoglycan can be used to estimate bacterial numbers. Such biochemical approaches for determining bacterial numbers depend on the development of analytical chemical procedures for quantifying the particular biochemical and determining what proportion of bacterial cell is composed of the specific biochemical constituent.

Spectrophotometers are electrical appliances that can measure turbidity very accurately. The culture is placed in a translucent cuvette; the cuvette is placed in the machine and the turbidity measured immediately (shown in Fig. 10). Simple mathematical formulae help convert the detected turbidity to cell concentration.

Preserving bacterial cultures

The preservation of microorganisms plays a key role in ensuring reproducible results and continuity in research. Maintaining a library of microbial stocks also enables microorganisms to be easily stored and retrieved, as compared to continuously sub-culturing

Spectrophotometer and its principle

Fig. 10 Spectrophotometer and its mechanisms of measurement.

microbial cultures on plates or in tubes. Depending on the length of storage and type of microorganism, different preservation methods are used. The underlying principle of long term preservation is to keep microorganisms in a dormant state, free from contamination and genetic changes, until ready to be brought back to life later. This is conventionally accomplished by using low temperatures, and freezing or drying techniques to reduce cellular metabolic activity. More recently, microencapsulation has also been explored as a novel method of microbial preservation for probiotic applications.

Short term storage (continuous growth)

Continuous growth of microorganisms can be maintained for short periods of time on agar medium. Agar plate cultures of microorganisms are viable for a few weeks when kept in the laboratory refrigerator (4 °C), while bacterial cultures can be stored for up to a year at 4 °C as agar stab cultures (Fig. 11). Most microorganisms (bacteria, fungi, and algae) can be stored using this method and it is recommended for cultures which are used regularly. Using nutrients from the culture media, these cultures grow continuously, albeit at a slower rate at lower temperatures, enabling them to survive for a longer time on the available nutrients.

To minimize contamination and drying of the agar, culture plates should be securely wrapped with laboratory film and stored upside down (agar side up). Tubes and vials containing agar stab cultures should be securely capped. An advantage of short term storage on agar medium is that it is easy to recover the microorganisms later. Just streak them onto fresh culture plates or inoculate them into liquid culture medium and incubate at the optimum growth temperature.

However, over a prolonged period of time, the agar dries up and nutrients in the culture media are depleted by the microorganisms. Metabolic waste products also accumulate to toxic levels. Nutrient starvation and toxic waste product build-up eventually cause the death of the stored microorganisms.

Long term storage

For long term storage, microorganisms are cryopreserved at temperatures below freezing (−20 °C, −80 °C, or liquid nitrogen) or freeze dried (lyophilized). Cryopreservation is suitable for a wide range of bacteria, algae, fungi, viruses, and protozoa. Ultralow temperatures drastically reduce enzymatic activity and, thus, metabolic processes of microorganisms. To prevent damage to cells caused by ice crystal formation, cells are resuspended in growth media containing cryoprotectants such as glycerol prior to storage at −20 °C, −80 °C, or in liquid nitrogen (−196 °C). Alternatively, cells can also be resuspended in skim milk before being frozen (Cody et al., 2008). To maximize the recovery rate, it is recommended to freeze cultures at the stationary phase of growth when cell concentration is highest. Most cultures can be stored in cryogenic vials (Fig. 12) at −20 °C for at least a year, with some bacterial stocks remaining viable for several decades when stored at −80 °C and in liquid nitrogen. Frozen microorganisms can be revived by thawing at 37 °C and inoculating into fresh culture medium (Tedeschi and De Paoli, 2011).

Freeze drying (lyophilization) removes moisture from frozen samples by converting water into ice in a vacuum, thus arresting microbial metabolic processes and transforming cells into dry pellets for convenient storage and transportation in ampoules (Fig. 13). Freeze drying has been used to preserve bacteria, algae, yeasts, viruses, and sporulating fungi (Prakash et al., 2013). However, lyophilization is not suitable for certain bacteria and non-sporulating fungi as they cannot survive the stresses of freeze drying. Lyophilized cultures can be recovered by rehydrating the cell pellets in growth media (bacteria and algae), growth medium containing the bacterial hosts (bacteriophages), or water (fungi and yeasts) before inoculating into fresh culture media.

Preserving microorganisms using microencapsulation

Microencapsulation, where cells are entrapped in a matrix prior to storage, has been proposed as a long term microbial preservation method which does not expose the microorganisms to the harsh stresses of freezing and drying. The matrix shields the cells and increases stability during storage. Microencapsulation of probiotic bacteria in calcium alginate has been shown to improve their viability when stored at −80 °C. Electrospinning and electrospraying, where microorganisms are trapped in nanofibers and droplets

respectively, have also been used to preserve the viability of sensitive probiotic bacteria (Alonso, 2016). Microbial preservation techniques enable the viability of microorganisms to be maintained, paving the way for their potential to be explored for years to come. With the right methods, some of these microorganisms may still be around in freezers long after we are gone, waiting to be revived by future generations of researchers.

Yeast & mold culture media

Yeasts are commensal and are widely found in human cavities, mucosa and digestive tracts. They can become pathogenic and engender opportunistic infections when favorable conditions arise in the host body, such as when the immune system is weakened. Opportunistic fungal infections range from superficial mycosis, which are localized skin and soft tissue infections to invasive mycosis, which can cause disease in almost any organ system. Although *Candida albicans* is still the most commonly found pathogenic yeast species, it is now also important to clearly identify other resistant *Candida* species which cause superficial and/or invasive infections, such as *Candida glabrata* and *Candida krusei*.

Fungi can be broadly classified into two groups; yeasts and molds. Yeasts are single-celled organisms that reproduce by budding but molds grow as filaments like structure. Many medically important fungi show unique behavior based on the temperature of growth and habitat, which is known as dimorphism (di: both, morphism: morphological form). These dimorphic fungi exist as molds in the environment at ambient temperature (25 °C–30 °C) and as yeasts (or other structure e.g., spherules in case of *Coccidioides immitis*) in human tissues at body temperature (35 °C–37 °C). Most of the dimorphic fungi cause systemic mycoses and *Sporothrix* (one of the dimorphic fungus) causes subcutaneous mycoses. Among the subcutaneous mycoses causing fungi, *Sporothrix schenckii* is a notable dimorphic fungus. It causes sporotrichosis. *Penicillium marneffe* is a mold and an opportunistic pathogen causing systemic penicilliosis in AIDS patients in Southeast Asian countries. Approximately 8% of nosocomial infections have a fungal origin, generally linked to the *Candida* genus. More commonly pathogenic yeast species includes *Candida albicans* and

Cryptococcus neoformans and genera that may cause severe infections in some high-risk patients: Dermatophytes: (*Microsporum*, *Epidermophyton*; *Trichosporon*), *Saccharomyces* and *Rhodotorula*.

Yeasts are able to grow on routine bacteriological media, such as blood agar and chocolate agar plates. If yeasts are present together with a mixed bacterial population, it is, however, possible that bacteria will suppress yeast growth. It is therefore generally accepted that a selective medium such as Sabouraud agar should be used for the cultivation of yeasts from clinical specimens (Merz and Roberts, 1995).

Two general types of culture media are essential to ensure the primary recovery of all clinically significant fungi from clinical specimens. One medium should be non-selective (such as Brain Heart Infusion Agar; i.e., one that will permit the growth of virtually all clinically relevant fungi) and other media should be selective, specially tailored to isolate specific pathogenic fungi of interest. For optimal recovery of fungal pathogen, a battery of media should be used, and the followings are recommended:

1. Media with or without cycloheximide (cycloheximide is added to inhibit the growth of rapidly growing contaminating molds.)
2. Media with or without an antibacterial agent (chloramphenicol, gentamicin and ciprofloxacin are commonly used antibacterial for this purpose).
3. Antibacterial agents are used to kill the contaminating bacterial species. If the sample is taken from sterile site, it is not necessary to use media containing antibacterial agents (Table 4).

Virus and phage culture media

In the early 1900s, viruses were isolated using embryonated eggs and laboratory animals. Cell cultures are typically generated from tissue samples and then disaggregated using mechanical, chemical, and enzymatic methods to extract cells suitable for virus isolation. The use of laboratory animals in research has declined dramatically as a result of the use of cell culture technology (Freshney, 2000). Furthermore, the number of viruses indexed has increased significantly as a result of the selection of appropriate cell lines. The isolation of viral pathogens in cell cultures began in the 1960s, but there were some drawbacks at the time, including a lack of facilities for diagnosing viral infections. The commercial invention of purified reagents and cell lines in 1970 opened a new window for viral infection diagnosis (Hsiung, 1984). Many human viruses were grown in vitro after cell culture was discovered. Cell culture is more convenient and cost-effective than using eggs or poultry. For virus isolation and detection, this approach is considered the gold standard (Hsiung, 1984).

Virus culture media

A range of media have been formulated for growth of vertebrate cells in culture. These incorporate various concentrations of amino acids, vitamins, enzymes, growth factors, and inorganic salts. Glucose, fructose, or galactose are also added along with glutamine to provide a carbon source for cell metabolism. There is a variety of formulations for cell culture media:

- Dulbecco Minimal Essential Medium (DMEM) is in common use for continuous cell lines.
- CMRL medium is particularly suited for the propagation of semi continuous cell lines.
- RPMI 1640 is recommended for growth of Lymphoblastoid cells in suspension.

Table 4 Commonly used yeast and mould culture media.

Brain-heart infusion (BHI) agar	It is a non-selective fungal culture medium that permits the growth of virtually all clinically relevant fungi. It is used for the primary recovery of saprophytic and dimorphic fungi
Czapek's agar	It is used for the subculture of <i>Aspergillus</i> species for their differential diagnosis.
Inhibitory mold agar (IMA)	Primary recovery of dimorphic pathogenic fungi. Saprophytic fungi and dermatophytes will not be recovered.
Mycosel/Mycobiotic agar	It is generally Sabouraud's dextrose agar with cycloheximide and chloramphenicol added. It is used for the primary recovery of dermatophytes.
Niger Seed Agar	It is used for the identification of <i>Cryptococcus neoformans</i> .
Potato Dextrose Agar (PDA)	It is a relatively rich medium for growing a wide range of fungi.
Sabouraud's Heart Infusion (SABHI) agar	Primary recovery of saprophytic and dimorphic fungi, particularly fastidious strains.
Sabouraud's dextrose agar (SDA)	Sabouraud's agar is sufficient for the recovery of dermatophytes from cutaneous samples and yeasts from genital cultures. Not recommended as a primary isolation medium because it is insufficiently rich to recover certain fastidious pathogenic species, particularly most of the dimorphic fungi. Sabouraud's dextrose agar (2%) is most useful as a medium for the subculture of fungi recovered on enriched medium to enhance typical sporulation and provide the more characteristic colony morphology.
Potato flake agar	Primary recovery of saprophytic and dimorphic fungi, particularly fastidious and slow-growing strains.

Conditions for growth of cell cultures

Optimum pH

A pH range of 7.1–7.5 is required for the growth of eukaryotic cells. Most culture media use bicarbonate buffer systems (CO_2/HCO_3) to maintain pH. These media are formulated with NaHCO_3 and CO_2 is either provided by the cultured cells as a metabolic product or by enrichment of the atmosphere using a CO_2 incubator. It is common to supplement the bicarbonate buffer system with HEPES buffer, it overrides all other buffers present and obviates the need for CO_2 enriched atmosphere.

Osmolarity

The growth of cells in culture depends on an optimum range of osmotic pressures, usually between 280 and 320 mmol/kg.

Serum

Balanced salt solutions will support cell proliferation only when supplemented with serum, lactalbumin hydrolysate, or other supplements. The serum provides essential amino acids, nucleic acid precursors, and fatty acids and also provides hormones and inhibits the protease used for routine dissociation of cells for culture. Fetal or newborn calf serum are used at conc. 5–15% to promote cell growth and at reduced conc. of 0–2% for maintenance of confluent monolayer cultures. Serum should be stored at -70°C , repeated freezing and thawing should be avoided.

Antibiotics

Antibiotics providing broad spectrum protection from bacterial contaminants are: benzylpenicillin, 20–100 units/mL, gentamicin, 16–50 $\mu\text{g/mL}$, and tetracycline, 10 $\mu\text{g/mL}$, Amphotericin B, 0.5 $\mu\text{g/mL}$, or nystatin, 50 units/mL, are recommended for control of fungal infections. Stock solutions should be stored at -20°C .

Isolation of viruses

Viruses, unlike bacteria, which can be grown on a synthetic nutrient medium, require a living host cell to replicate. Infected host cells (eukaryotic or prokaryotic) can be cultured and grown, and the growth medium can then be harvested for virus production. Centrifugation or filtration may be used to isolate virions in the liquid medium from the host cells. Filters will physically extract something larger than virions from a solution, allowing the viruses to accumulate in the filtrate (see Fig. 14).

Cultivation of viruses

Viruses can be grown *in vivo* (within a whole living organism, plant, or animal) or *in vitro* (outside a living organism in cells in an artificial environment, such as a test tube, cell culture flask, or agar plate). Bacteriophages can be grown in the presence of a dense layer of bacteria (also called a bacterial lawn) grown in a 0.7% soft agar in a Petri dish or flat (horizontal) flask (see Fig. 15). The agar concentration is decreased from the 1.5% usually used in culturing bacteria. The soft 0.7% agar allows the bacteriophages to easily

Fig. 14 Membrane filters can be used to remove cells or viruses from a solution. (A) This scanning electron micrograph shows rod-shaped bacterial cells captured on the surface of a membrane filter. Note differences in the comparative size of the membrane pores and bacteria. Viruses will pass through this filter. (B) The size of the pores in the filter determines what is captured on the surface of the filter (animal [red] and bacteria [blue]) and removed from liquid passing through. Note the viruses (green) pass through the finer filter. Credit A: modification of work by U.S. Department of Energy.

Fig. 15 (A) Flasks like this may be used to culture human or animal cells for viral culturing. (B) These plates contain bacteriophage T4 grown on an *Escherichia coli* lawn. Clear plaques are visible where host bacterial cells have been lysed. Viral titers increase on the plates to the left. Fig. 16 (A) The cells within chicken eggs are used to culture different types of viruses. (B) Viruses can be replicated in various locations within the egg, including the chorioallantoic membrane, the amniotic cavity, and the yolk sac. Credit A: modification of work by “Chung Hoang”/YouTube.

diffuse through the medium. For lytic bacteriophages, lysing of the bacterial hosts can then be readily observed when a clear zone called a plaque is detected (see Fig. 15). As the phage kills the bacteria, many plaques are observed among the cloudy bacterial lawn.

Animal viruses require cells within a host animal or tissue-culture cells derived from an animal. Animal virus cultivation is important for (1) identification and diagnosis of pathogenic viruses in clinical specimens, (2) production of vaccines, and (3) basic research studies. In vivo host sources can be a developing embryo in an embryonated bird’s egg (e.g., chicken, turkey) or a whole animal. The embryo or host animal serves as an incubator for viral replication (see Fig. 16). Location within the embryo or host animal is important. Many viruses have a tissue tropism, and must therefore be introduced into a specific site for growth. Within an embryo, target sites include the amniotic cavity, the chorioallantoic membrane, or the yolk sac. Viral infection may damage tissue membranes, producing lesions called pox; disrupt embryonic development; or cause the death of the embryo.

For in vitro studies, various types of cells can be used to support the growth of viruses. For example, HeLa and HEp2 are used for cultivation of HSV, adenovirus, poliovirus and some coxsackie viruses. Vero cells will also support growth of these viruses and are used with BHK21 cells for growth of arboviruses. RK13 cells and BHK21 cells for isolation and propagation of *rubella virus*. RD cells for the isolation of *coxsackie A virus*.

A primary cell culture is made from animal organs or tissues that have been freshly prepared. Mechanical scraping or mincing to release cells or an enzymatic process using trypsin or collagenase to break up tissue and release single cells into suspension are used to extract cells from tissues. Because of the need for anchorage, primary cell cultures require a liquid culture medium in a Petri dish or tissue-culture flask so that the cells can adhere to and expand on a solid surface such as glass or plastic. The lifespan of primary cultures is usually short. A secondary cell culture is when the cells from a primary cell culture are moved to a new vessel with fresh growth medium. Cell density must be decreased on a regular basis by pouring off some cells and replacing them with fresh medium to provide space and nutrients for cell development. Continuous cell lines, which are normally produced from transformed cells or tumors, may also be subcultured several times or even grown indefinitely, in comparison to primary cell cultures. As a consequence, continuous cell lines may form lumps or piles that resemble small tumors (see Fig. 17).

The HeLa cell line, which was originally cultivated from tumor cells derived from Henrietta Lacks, a woman who died of cervical cancer in 1951, is an example of an immortal cell line.

Fig. 17 Cells for culture are prepared by separating them from their tissue matrix. (A) Primary cell cultures grow attached to the surface of the culture container. Contact inhibition slows the growth of the cells once they become too dense and begin touching each other. At this point, growth can only be sustained by making a secondary culture. (B) Continuous cell cultures are not affected by contact inhibition. They continue to grow regardless of cell density. Credit “micrographs”: modification of work by Centers for Disease Control and Prevention.

HeLa cells were the first continuous tissue-culture cell line, and they helped to develop tissue culture as a valuable tool in cell biology, virology, and medicine research. Prior to the discovery of HeLa cells, scientists were unable to reliably and consistently create tissue cultures. This cell line is still alive and being used for medical research after more than six decades.

Glossary

Antigen Pathogen or a component of the pathogen recognized by antibodies.

Introduction

This article describes tests used to detect antibodies formed in response to infection. The predominant purpose for which antibody tests are applied is diagnosis. Antibody tests provide a longer diagnostic window than direct pathogen detection methods and therefore provide information about the etiology of an infection after the acute phase when the pathogen or its components can no longer be detected. For some viruses in particular, for example in some human flavivirus infections with no or only transient viraemia, diagnosis can be heavily reliant on detection of antibodies. Typically, antibodies are measured in serum samples (serological tests). However, other clinical samples can be used, for example detection of antibodies in cerebrospinal fluid can help determine that a pathogen is the causative agent of neurological signs such as encephalitis.

Many antibody tests do not distinguish between immunoglobulin classes. Although immunoglobulin A (IgA) antibodies are important in the immune response against mucosal pathogens, most tests measure IgM and/or IgG antibodies. IgM is produced rapidly after an individual is first exposed to a pathogen, but levels also decline relatively rapidly (Fig. 1). Therefore, a test that is specific for IgM antibodies is useful for confirming a recent or active infection. The production of IgG antibodies starts a short time after IgM and typically lasts longer. An IgM response is generally not detected in a reactivated infection or re-infection, whereas the anamnestic IgG response is usually greater and longer-lasting than the primary response. Therefore, to distinguish whether IgG antibodies are present in a sample due to recent infection or previous exposure (either from infection or vaccination) it is often necessary to demonstrate a significant increase in IgG between two samples taken 7–10 days apart (seroconversion).

Antibody tests are also used in epidemiological studies. The true prevalence of a disease is an essential parameter to appraise the impact on a population, for example to decide whether to implement disease control programs. Serosurveillance can also be important for disease eradication programs. In the veterinary field, demonstrating that a livestock population is free from infection can have important trade implications. A further application of antibody tests is to monitor vaccine responses, for which the ability of antibodies stimulated by vaccination to neutralize infectivity of the pathogen is usually the most relevant measure of vaccine efficacy (in a controlled trial) or effectiveness (under field conditions).

Most antibody tests do not provide an absolute measure of the total amount of pathogen-specific antibody present in a sample. Antibody tests that involve performing a serial dilution of the sample provide a titer. For example, a titer of 1:40 indicates the last sample dilution at which the antibody has the effect that provides the read-out for the test (for example neutralization of virus infectivity) and does not indicate the amount of non-neutralizing antibodies present. Other assays such as the enzyme-linked immunosorbent assay (ELISA) provide a read-out that is a value proportional to the amount of antibody in a sample that binds specifically to the pathogen or a component of the pathogen. Limitations of the antibody tests include where cross-reactivity between antibodies to closely-related pathogens does not allow unambiguous interpretation of the results. In addition, in infants, maternally-derived antibodies may be present.

Fig. 1 Representation of immunoglobulin M (IgM) and IgG responses after primary and secondary infections. Modified from Murphy K, Travers P, Walport M and Janeway C (2008) *Janeway's Immunobiology*. New York: Garland Science.

Techniques for antibody detection

Neutralization tests

Neutralizing antibody tests are widely used in the field of virology. Most tests involve incubating a sample with a known amount of infectious virus for a short period before measuring the residual infectivity. A relatively straightforward virus neutralization test (VNT) involves titrating virus infectivity on a susceptible cell line that shows visible cytopathic effect (CPE) in a 96-well plate to obtain the 50% tissue culture infective dose (TCID₅₀) calculated using the Kärber or another similar formula. The virus is then diluted to a standardized amount and an equal volume of virus and serially diluted sample is then incubated typically for 30 min at 37 °C before adding the mixture to a cell monolayer and incubating for up to 4 or 5 days to obtain a readout. The virus-neutralizing antibody titer is presented as the highest dilution of serum at which no or <50% cytopathic effect is observed (Fig. 2). For viruses that do not have a discernible cytopathic effect, an additional test may need to be performed to determine whether virus replication has been reduced by the presence of antibodies, for example by immunostaining with a specific antibody or detecting viral genetic material by PCR or reverse transcription-PCR. This increases the cost and complexity of the test.

In recent years, some of the drawbacks of the VNT have been circumvented by using pseudotyped viruses. A pseudotyped virus (PV) typically consists of a retroviral core with the surface protein (or proteins) from the virus of interest packaging a reporter gene (e.g., luciferase). To generate an HIV-based PV, two protein plasmids expressing the surface protein of the virus of interest and HIV core structural proteins, and a third plasmid with a ψ packaging signal and reporter gene, are co-transfected into producer cells, typically human embryonic kidney (HEK) 293T cells (Fig. 3; Mather et al., 2013). The HIV core proteins and surface protein assemble into virus-like particles containing an RNA dimer of the reporter gene as the only genetic material. The PV can transduce

Fig. 2 Example of a virus neutralization test result. Briefly, serially-diluted bovine serum samples were incubated with 100 TCID₅₀ (50% tissue culture infectious doses) of Schmallenberg virus in duplicate for 1 h before adding Vero cells to each well. After 5 days' incubation, the cells were ethanol fixed and stained with 0.1% methylene blue. Samples 1 and 2 are antibody positive, samples 3 and 4 are antibody negative.

Fig. 3 Schematic of production of a pseudotyped virus with an HIV core and luciferase reporter gene. (A) Plasmid DNA expression vectors bearing (i) the HIV gag-pol gene, (ii) the envelope protein from the virus of interest or (iii) a reporter gene (e.g., luciferase) are generated. (B) All three plasmids are transfected into “producer” cells (e.g., HEK293 T cells). (C) Supernatants are harvested at 48 h post-transfection and produced pseudotype viruses (PVs) are titrated on target cells expressing receptors recognized by the envelope protein in order to ascertain a relative transduction titer. (D) PVs can be subsequently employed as surrogate viruses in pseudotype neutralization assays. Titrated patient samples are preincubated with a fixed titer of PV before addition to target cells. Binding of the envelope protein by specific antibodies in the sample blocks entry of the PV into the target cell, thus preventing expression of the reporter gene. As for traditional plaque reduction neutralization tests, the titer of antibody can be expressed as the highest dilution of sample that inhibits expression by 50% or 90%. LTR: Long tandem repeat. Created with BioRender.com. Adapted from Mather S, Scott S, Temperton N, Wright E, King B and Daly J (2013) Current progress with serological assays for exotic emerging/re-emerging viruses. *Future Virology* 8: 745–755.

(“infect”) target cells expressing receptors recognized by the surface protein. Long tandem repeats (LTRs) flanking the reporter gene direct integration of the gene into the target cell genome resulting in expression of the reporter protein, which is detected by addition of a suitable substrate after a 2- to 3-day incubation period. In a pseudotyped virus neutralization test (PVNT), the incubation of the PV with samples containing antibodies before transduction of target cells results in a reduction in reporter signal. Using a PV as a “surrogate” virus in a neutralization test provides a readout for viruses that do not cause CPE and avoids the need to handle hazardous infectious virus. In fact, synthesis of the gene for expression of the surface protein of interest obviates the need to obtain the virus. There is also the potential to multiplex PVNTs to measure antibodies to different viruses simultaneously by incorporating different reporter genes, such as Renilla or firefly luciferase, into PVs with different surface proteins (Molesti et al., 2014).

The plaque reduction neutralization test (PRNT) is a more accurate, but also technically more complex, test. The virus is inoculated onto a cell monolayer, but a semi-solid overlay is added to prevent spread of the virus in the media. This results in “plaques”, which are small areas of CPE caused by direct cell-to-cell spread of virus from a single infected cell (Fig. 4). The antibody titer obtained is usually expressed as the dilution of sample that reduces the number of plaques obtained at a specific dilution of virus by a certain percentage (e.g., 50% or 90%), which can be interpolated from a plot of sample dilution against number of plaques.

Fig. 4 Example of a plaque titration of virus to determine amount of virus to incubate with samples in a plaque reduction neutralization test. Briefly, Vero cells were infected with 10-fold dilutions of Schmallenberg virus and overlaid with carboxymethylcellulose. After incubation for 4 days, the cells were fixed with 10% neutral buffered formalin and stained with methylene blue solution.

Although neutralizing antibody tests are specific and sensitive, they are time-consuming and laborious, and therefore not widely used in routine diagnostic services. However, they are regarded as a gold standard test and are often used as a confirmatory test where it is difficult to distinguish between cross-reactive antibodies against closely related viruses (such as members of the flavivirus family). As previously mentioned, measurement of antibodies that decrease the infectious capacity of a pathogen is an important measure of the potential protection afforded by vaccination.

Immunodiffusion

Antibodies were first detected by their ability to precipitate antigen when mixed at equivalence (i.e., the optimal amount of antibody and antigen is present; Fig. 5). In the double diffusion or Ouchterlony technique (Ouchterlony, 1948), antigen and antibody are placed in adjacent wells punched out of agarose gel. Precipitation occurs when the two diffuse out of the wells and meet at appropriate concentrations. The technique is cheap and simple but not particularly sensitive.

Agglutination tests

If an antigen is particulate, e.g., a bacterial surface antigen, agglutination of the particles by the addition of antibody can provide a simple detection system. For example, the *Treponema pallidum* particle agglutination assay (TPPA) is used to confirm a diagnosis of syphilis. The hemagglutination inhibition (HI) test remains a common method for detecting antibodies to viruses such as influenza A viruses. The test relies on the virus binding to receptors on the surface of red blood cells and causing them to aggregate (agglutination). Similarly to the VNT, a standardized amount of virus (e.g., 4 hemagglutinating units) is incubated with dilutions of sample. A suspension of red blood cells is then added and after a further incubation period, the HI titer is determined as the highest sample dilution that inhibits agglutination of the red blood cells by the virus. Alternatively, pathogen proteins can be coupled to inert particulate carriers such as latex beads. The latex agglutination test is sensitive, easy to perform and inexpensive. It is therefore highly suitable for use in the field (as a point-of-care test) and in less-developed countries. The tests are more sensitive to the detection of IgM antibodies, because they are polymeric, and therefore valuable for diagnosing recent infection.

Complement-dependent assays

The complement system is a group of heat-labile proteins that bind to antigen–antibody complexes. When this interaction occurs on a cell surface, it results in the formation of transmembrane pores causing lysis of the cell. The complement fixation (CF) test is a classical laboratory diagnostic test that relies on the fact that the amount of complement “fixed” is proportional to the amount of antibody in the complex and the remaining complement can be measured in a hemolytic assay. Complement present in serum samples is heat inactivated before mixing serial dilutions with antigen and incubating to allow antigen–antibody complexes to form. Exogenous complement is then added (usually from guinea pig serum). Usually sheep red blood cells coated with anti-sheep red blood cell antibody are then added to measure the hemolytic activity of any residual complement. The titer is the highest dilution of sample that fixes all of the added complement (therefore there is no complement remaining to lyse the sheep red blood cells). The single radial hemolysis (SRH) assay is another complement-dependent assay in which sheep red blood cells are coated with antigen and mixed into molten agarose with guinea pig complement. The agarose is poured into a plastic mold and after it has set, wells are punched into the agarose into which heat inactivated serum samples are added. The plates are incubated to allow the sample to diffuse from the well. The area of the clear zone surrounding wells where complement-mediated lysis of the red blood

cells occurs is directly proportional to the amount of antibody present in the sample (Fig. 6). Antibodies against influenza A viruses measured by SRH have been shown to correlate with protection.

Immunoassays

Immunoassays involve using labeled antibody reagents. In the past, radioimmunoassays used radio-isotope labels such as ^{125}I . Today, the enzyme-linked immunosorbent assay (ELISA) has largely superseded the tests described so far for antibody detection because it is relatively simple to perform, rapid and affordable.

Enzyme-linked immunosorbent assay (ELISA)

The ELISA was first described by Engvall and Perlmann (1971). The assay is performed by immobilizing the reagents, typically in 96-well or 384-well polystyrene microtiter plates, which passively bind antibodies and proteins. The presence of the target macromolecule is detected directly or indirectly using an enzyme-linked specific antibody. In its simplest form (direct ELISA), four incubation steps are performed:

- (i) Coating: In a direct ELISA, the sample is added directly to wells of a microtiter plate to immobilize the antigen. After incubation, the wells are thoroughly washed.
- (ii) Plate blocking: A solution containing an irrelevant protein is added (e.g., bovine serum albumin or non-fat milk) to cover any unoccupied surfaces on the microtiter plate, preventing the detection antibody from binding non-specifically to the plate surface.
- (iii) Detection: A labeled antibody, which is specific for the target macromolecule and has a reporter enzyme conjugated to it, is added. The wells are again thoroughly washed to remove any unbound detection antibody.
- (iv) Signal measurement: Finally, an appropriate substrate for the enzyme conjugated to the detection antibody is added. If the detection antibody has bound to its specific target, the action of the enzyme on the substrate will produce a detectable signal. The most common system for signal measurement involves one of two enzymatic labels (horseradish peroxidase (HRP) or alkaline phosphatase (AP)) with a choice of substrates that undergo a color change that is detected by measuring the absorbance at a specific wavelength in a plate reader (spectrophotometric readout).

Advantages of the ELISA include the use of highly specific antibodies and washing away non-specific components and the flexibility of the format. The direct ELISA described above is rarely used for antibody detection. In the indirect ELISA for antibodies (Fig. 7), the microtiter plate is coated with antigen from the pathogen (or the pathogen itself), the sample is added and pathogen-specific antibodies in the sample are detected by a labeled anti-IgG antibody. Although IgM can be detected in the same format, because IgG is usually of higher affinity and may be present in higher amounts, it can block binding of IgM and needs to be removed from the sample. Therefore, IgM antibodies are usually detected using a “sandwich” ELISA format. In this format, the microtiter plate is coated with anti-IgM antibody, which captures all IgM antibodies in the sample. Antigen is then added, which will be bound by any pathogen-specific IgM captured on the surface of the microtiter plate. Finally, a detection antibody that recognizes the antigen is added followed by the appropriate substrate.

In the veterinary field, competitive ELISAs are used to detect antibodies against pathogens that may affect multiple species. In its simplest format, the competitive ELISA measures the reduction of signal obtained when antibody present in the sample competes with labeled detection antibody to bind antigen coated on the microtiter plate compared to binding of the labeled antibody in the absence of competing antibody. Thus there is no requirement for a species-specific detection or capture antibody as there is in the indirect and capture ELISA, respectively.

Fig. 7 Schematic of the most common ELISA formats used for measuring antibodies. Modified from a BioRender.com template.

Multiplex assays

There is an increased rate of emergence of novel pathogens, particularly viruses, and consequently an increase in pathogens with overlapping geography. There is also a need to distinguish between pathogens that cause similar clinical disease. For example, in regions where different flaviviruses co-circulate, an IgM antibody capture ELISA (MAC-ELISA) is often applied in which the sample is added in parallel to wells coated with different virus antigens and the infecting virus is taken to be that coated in the well giving the highest signal (e.g., *Lewthwaite et al., 2010*).

Measuring antibodies against multiple pathogens by ELISA in parallel is time consuming, increases the risk of error and uses larger volumes of sample (a key challenge if, for example, performing diagnostic tests on CSF from a child).

One approach to multiplex an assay is to spatially separate reagents, for example by immobilizing capture antibodies in small arrays at the bottom of individual wells of microtiter plates. Another approach is to immobilize reagents on beads. For example, Luminex[®] technology uses combinations or levels of dyes to individually code up to 500 batches of beads. A capture assay is performed by coating beads with different antibodies, incubating these with the sample and using phycoerythrin-labeled detector antibodies to measure protein levels. A disadvantage of this technique is the requirement for a specialized flow cytometer to read the assay and proprietary software to decode the sample signals, although similar assays with a more limited number of codes are possible with standard flow cytometers.

Lateral flow test

Lateral flow tests are another variation of the ELISA in which antigens are immobilized on a strip of cellulose or other suitable matrix. The sample is applied at one end of the strip and any antibodies present diffuse along it until they reach the position where the appropriate antigen is immobilized. Antibodies specific for the antigen bind to and remain at the site of the antigen and are visualized using labeled detection antibody. The lateral flow test is not quantitative, but is rapid and simple to perform, making it a suitable point-of-care test. The nitrocellulose strip is typically housed in a plastic casing with an opening where the sample and reagents are applied and a window where the result is read. Usually, a positive control antigen is placed on the strip so that it is encountered after the test antigen to confirm that the sample has diffused a sufficient distance to interact with the test antigen. More than one test antigen can be dotted on the strip to provide a multiplex test. IDEXX Laboratories, Inc., a veterinary company, has developed a lateral flow test casing that incorporates reagent reservoirs. After the sample has diffused along the strip to an "activation window," the end of the device is pressed down to puncture the film across the reservoirs, releasing their contents, which mix with the sample and are drawn back across the strip. This is reported to improve sensitivity as the sample passes across the antigen twice and specificity as debris is washed from the result window. The SNAP test range includes tests to detect antibodies to parasites and to detect antibodies to feline immunodeficiency virus and feline leukemia virus antigen in the same test.

Development of antibody tests

Validation is a process to determine fitness of an antibody test for its intended purpose(s). The requirements of an antibody test may be more stringent if it is intended to be used for diagnosis of disease in an individual with implications for their subsequent treatment or to gain an idea of the prevalence of a disease in a population.

Sensitivity (Se) and specificity (Sp), which indicate the probability that a truly infected individual yields a positive or a negative result, respectively, are the most commonly used performance indicators of a diagnostic test. Usually, Se and Sp are estimated by screening a panel of “known” positive or negative samples. This panel can be from individuals for which historical and accurate information indicates that they were infected (e.g., known to have had clinical signs and in whom the specific pathogen was identified) or not. In the development of antibody tests for veterinary applications, it may be possible to obtain samples from experimentally infected animals. More often, they are samples that have been identified as positive or negative using a gold standard test (for which Se and Sp are regarded as 1). A more cautious approach is to use multiple alternative tests to reduce misclassification errors.

Determining the threshold or cut-off value above which a test can be regarded as positive may often be somewhat arbitrary. For example, frequently in the development of ELISAs, a threshold of the mean of negative control values plus two standard deviations is used. As a result, ELISAs often have a range of test values between the negative and positive thresholds that have to be regarded as “inconclusive.”

Properly validated antibody tests should be repeatable (i.e., have good agreement between results of replicates of a sample within and between test runs in the same laboratory) and reproducible across laboratories. Achieving reproducibility is hampered where tests involve the use of cell line or other potentially variable materials (e.g., red blood cells) obtained from different sources. International reference standards can help achieve standardization. Inter-laboratory trials can be conducted in which several laboratories are supplied with candidate reference standards and a standardized protocol. The results obtained from multiple independent tests in each laboratory are statistically analyzed to assign an expected value to the reference material.

The future of antibody tests

Many of the antibody tests still in use today were first developed decades ago. Major advances have been made in the development of antibody tests. There is an increasing focus on the use of non-invasive samples such as saliva, urine or milk. These can be more difficult substrates to work with than serum in traditional antibody tests, for example milk samples can be toxic to the cells used in virus neutralization tests, but can be used in ELISA and similar tests. Point-of-care tests such as easy-to-use lateral flow or latex agglutination tests that provide a result in minutes are becoming increasingly common in clinical practice. Nonetheless, there is often a trade-off between convenience, speed and high throughput on the one hand and sensitivity and specificity on the other. The increasing rate of emergence of infectious diseases, particularly viral diseases means that there is an increasing demand for tests that can be rapidly developed to reliably detect antibodies to novel pathogens. For example, the COVID-19 pandemic caused by SARS-coronavirus 2 has led to the PVNT becoming a more widely accepted technique.

In veterinary medicine in particular, there has been a move towards developing antibody tests that complement a new generation of recombinant vaccines. The differentiation of infected from vaccinated animals (DIVA) strategy involves employing an antibody test that detects antibodies to proteins that are not present in the vaccine. This enables vaccination to be used to control an outbreak while still enabling infected animals to be identified. Where it is not possible to distinguish whether antibodies are a result of infection or vaccination, vaccination can lead to trade restrictions being imposed if it is uncertain whether disease is circulating in a country or not. It is likely that in future, similar strategies will be increasingly relevant in human medicine.

Introduction

Flow cytometry (FCM) is a laser-based technology used for multiparametric analysis of biological particles. Particles in the form of a suspension/solution (blood, bone marrow, lymphoid tissue, fluids) are passed through a “flow” chamber which is illuminated by a laser source. The signals generated while passing through this chamber are collected by optical and electronic systems and analyzed by a computer control system. The simplified design of the FCM is shown in Fig. 1.

In history, the device, first described by Andrew Moldavan in 1934, has been accepted as an early prototype (Moldavan, 1934). In time, with the developing technology and new ideas, the device began to be made suitable for today's medicine between 1969 and 1972 (Van Dilla et al., 1969; Julius et al., 1972). At the beginning of the 21st century, with the development of laser, optical and electronic systems, it has started to be used in many areas. Nowadays, FCM is used as a diagnostic and research method in multiple disciplines such as immunology, hematology, oncology, microbiology, pathology, histology and biochemistry laboratories (Figs. 2–5).

In the basic working principles of FCM, each particle in the sample is evaluated for visible light scatter and multiple fluorescence parameters. Visible light scatter is measured by two optical detectors; forward scatter (FSC) and side scatter (SSC). FSC detects scatter along the laser path and these signals can be used to define the relative size of the cell. SSC measures scatter at 90 degree angle relative to the laser, which indicates the internal complexity or granularity of the cell. Furthermore, samples are prepared for fluorescence measurement, which permits visualization of cellular features or structure, for expression of fluorescent proteins, staining with fluorescent dyes or immunostaining with fluorescently conjugated antibodies (McKinnon, 2018). Thus, with the data obtained with nonfluorescent and fluorescent signals; we can determine size, granularity, enzyme activities, fluorochromes (fluorescent antibody), immunophenotype, membrane potential and DNA contents about particles.

By this dynamic and powerful system, thousands of individual particles can be evaluated quickly and objectively at high speed. Therefore, FCM has been increasingly used in medical diagnosis and prognosis over the last decade. In recent years, FCM has become a daily used scientific instrument in immunology and hematology clinical departments for differential cell counts of leukocyte populations, identify an antigen of interest, characterize expression profiles in several different subsets of cells or determine the cell cycle status of a population (Robinson, 2004).

This article focuses on explaining the areas where FCM is used, the differentiation and development stages of B cells from stem cells to other cells by immunophenotyping method, and some clinical examples.

Practical applications of flow cytometry

FCM has many techniques and applications suitable for diagnosis, research, clinical trials and treatment monitoring for multiple fields of study. By far the most frequently used FCM application is immunophenotyping. For FCM applications, the particles must be sufficient size to be detected and have an appropriate fluorescent nature. For the fluorescent structure, fluorochrome-conjugated ligands that can bind to specific cell structures are used. With the demonstration of cells with fluorescent structure, several clinical assays can be performed. Some of these assays are shown in the Table 1.

Table 1 Common applications of flow cytometry.^a

Application	Examples	Approach
Immunophenotyping	Leukemia and lymphoma phenotyping	Fluorochrome-conjugated monoclonal antibodies
	PNH testing	
	Hematopoietic progenitor cell enumeration	
	CD4 counting	
Phagocytosis	Fetal hemoglobin detection	Fluorochrome-coated beads
	Neutrophil phagocytosis	
	Cell cycle analysis	
	Evaluation of apoptosis	
DNA analysis	Ploidy determination	Fluorescent dyes binding directly to DNA

Immunophenotyping studies

FCM facilitates the search for B-cell markers and provides information on important points in B-cell biology. It is also a powerful tool to drive the discovery of cell development, differentiation, immunodeficiency, autoimmune disorders and malignancies (McKinnon, 2018).

Immunophenotyping studies can be used to identify cell subsets, lineage, stage of cell differentiation, state of cell activation, and clonality (Fleisher and Oliveira, 2019). The various stages of B-cell differentiation can be identified by evaluating the expression and levels of distinct cell-surface markers, which are regulated throughout the course of B-cell differentiation (Fleisher and Oliveira, 2019). And also, FCM is a common method used for immunophenotyping, which can detect cells stained with fluorochrome-conjugated antibodies that are targeted against antigens on the cell surface. Therefore, FCM can be used to test for the presence or absence of a specific cell surface antigen.

Most of these antigens are given “cluster of differentiation” numbers or CD numbers so that a common nomenclature is used to define monoclonal antibodies (mAbs) that are directed against specific cellular antigens (McKinnon, 2018). These same CD markers are currently used to isolate these B cell subsets in order to study their function.

Cell cycle

The cell cycle is a sequence of events that takes place in many phases. During these phases, when there are alterations and dysregulation in the genetic content, which can be observed by fluorescent dye, it can lead to tumor formation. Therefore, monitoring of cell cycle can provide information for diagnosis and treatment of diseases.

With FCM, we can detect cell populations at different stages of the cell cycle, such as G0/G1, S, and G2/M. We can also identify apoptotic cells (Bajgelman, 2019).

Cell sorting

Cell sorting is used for the separation, isolation and purification of various cell populations, which can be made fluorescent, for more detailed multiparametric analysis. Moreover, with this technique, it is possible to measure the DNA and RNA content of cells and even evaluate functional properties.

This technique can be used in many situations such as stem cells in bone marrow samples, selection of sperm to allow sex selection, purification of different lineages, detection of tumor infiltrating lymphocytes, tumor cells and white blood cell populations (McKinnon, 2018).

Apoptosis

Apoptosis, also known as programmed cell death, is a tightly regulated biochemical process centered primarily around the caspases family of enzymes. During apoptosis, a series of events such as blebbing, cell shrinkage, pyknosis takes place. As a result of this programmed process, cells are lysed into apoptotic bodies.

FCM has become the method of choice for the detection and quantification of cellular apoptosis due to its rapid assessment of large numbers of cells (Fleisher and Oliveira, 2019). Thus, morphological, biochemical and molecular changes that occur in cells during apoptosis can be detected.

We can evaluate a cell that has started the apoptosis process with its light scattering properties. Decrease of FSC and increase of SSC can be observed by FCM. However, scattering changes are not unique to apoptosis alone. An additional feature associated with cell death needs to be demonstrated. In early apoptosis, cells lose asymmetry and phosphatidyl serine (PS) residues, which is positioned inside the plasma membrane, expose to the cells outer surface. Annexin V, which is a human vascular anticoagulant, has high affinity for PS. Conjugated annexin V is a widely used reagent in the detection of apoptotic cells (Fleisher and Oliveira, 2019). With the rupture of the cell membrane, the late apoptotic stage can be detected with different cationic dyes. Furthermore, with the combination of annexin V and cationic dyes, we can also determine at what stage the cells are in the apoptotic process.

Evaluation of mitochondrial transmembrane potential and measurement of DNA content are other methods that can be used to distinguish living cells from dead cells.

DNA content

Cellular DNA content can be measured by FCM. With this method; cell distribution within major phases of the cell cycle, assessment of apoptosis and determination of ploidy can be evaluated (Darzynkiewicz and Huang, 2004).

DNA can be stained with fluorescent dyes and hence, can be detected quantitatively by FCM due to its fluorescent property. The most commonly used fluorescent dye for this method is propidium iodide (PI). PI can bind all double-stranded nucleic acids. Therefore, RNAase must be added before staining to detect DNA content.

Other fluorescent dyes used for DNA content analysis are 4',6-diamidino-2-phenylindole (DAPI), dye cycle violet, Hoechst 33342, acridine orange, 7-aminoactinomycin D (7-AAD) and ethidium bromide (McKinnon, 2018; Fleisher and Oliveira, 2019).

B-cell

B cells are the central of humoral immunity and protection. The main function of B cells is to produce and release antibodies to specific antigens with antibody-secreting plasma cells and memory cells after antigen recognition. Secreted antibodies have the ability to neutralize almost unlimited variety of pathogens and their toxins. Furthermore, B cells have antigen receptors (BCR), immunoglobulin (Ig) receptors, adhesion molecules and Major Histocompatibility Complex (MHC) molecules on the surface. These surface molecules contribute to the regulation of B cell-related development, activation, proliferation, differentiation and effector functions by mediating communication with the extracellular microenvironment.

Various stages of B cell development and differentiation have become identifiable with the development of FCM analysis. Moreover, FCM has begun to identify and characterize expression profiles in several different subsets of B cells.

CD molecules involved in B cell development and differentiation are listed in Table 2.

Early stages and cells in the bone marrow

The generation of B cells begins in the bone marrow (BM) where multipotent hematopoietic stem cells (HSCs) are stimulated by lymphoid progenitors and cytokines. The first cells to be affected by lymphoid progenitors are called early (pre) pro-B cells. Early BM-dependent stages of B cell development are constructed through the functional rearrangement process of Ig gene segments. Thus, rearrangement of heavy and light chains (HC and LC) gene segments generates a repertoire of B cells expressing a vast number of antibodies that can recognize multiple different antigens. Progenitor B cells rearrange the Ig HC genes to differentiate into pre-B cells expressing μ HCs. Besides, pre-B cells undergo one or two cell divisions, and then rearranging the gene segments encoding the κ and λ chains (van Zelm et al., 2007). Also at this stage, positive selection is made for B cells with normal functional receptors. Pre-B cells then rearrange their Ig LC genes to differentiate into IgM⁺ immature B cells. At this stage, a negative selection mechanism is used to eliminate self-reacting B cells and minimize the risk of autoimmunity.

Immature B cells leave the BM and migrate to the spleen, where their final stages of maturation. When an immature B cell starts migrating into the periphery with the bloodstream, it first becomes a Transitional B (TB) cell which are considered to be precursors of mature B cells. And then, they become differentiating into naive, follicular (FO), or marginal zone (MZ) B cells in spleen.

Transitional B cells

TB cells are an important link between immature B cells in the BM and mature peripheral B cells. The newly produced immature B cells, which are called T1 B-cell, migrate from BM to spleen. After T1 B cells enter the spleen, cell surface molecules differentiate, and also, gain the ability to circulate (Suryani et al., 2010). These cells are known as T2/T3 B cells. After these stages, T2/3 B cells also differentiate into mature B cells (Suryani et al., 2010).

Follicular and marginal zone B cells

In the spleen, mature B cells are divided into two groups: FO B and MZ B cells. The difference and strength of BCR signaling pathways integrated with B cell-activating factor (BAFF) and Notch2 signaling determine the commitment of B cells from the TB cell to the mature FO B or MZ B cell fate (Cerutti et al., 2013).

Weak BCR signal, nuclear factor kappa B (NF- κ B) and Notch2 signaling are important for TB cells to develop into the MZ B cells, which are noncirculating mature B cell and anatomically located in the marginal zone of the spleen (Martin and Kearney, 2002). The functions of MZ B cells are; T cell dependent and independent responses to blood-borne pathogens, responses to lipid antigens with CD1d and collaboration with natural killer T (NKT) cells (Pillai and Cariappa, 2009). Furthermore, MZ B cells differentiate into short-lived plasma cells that produce large amounts of IgM (Balázs et al., 2002).

Strong BCR signal, BAFF and NF- κ B signaling are necessary for the TB cells to develop into FO B cells (Pillai and Cariappa, 2009). They are primarily located in the follicles of the spleen and lymph nodes. And also, FO B cells can recirculate through blood and lymphatics into secondary lymphoid organs, and back into the BM. FO B cells have more broader diversity of Ig genes than have MZ B cells (Cerutti et al., 2013). The main function of FO B cell is to mediate adaptive antibody production. Therefore, FO B cells interact with T helper (Th) cells to form germinal centers, and then, undergo class switching recombination (CSR) and somatic hypermutation (SHM). Along with these changes, FO B cells produce high affinity antibodies to eradicate pathogens or give rise to memory B cells (McHeyzer-Williams and McHeyzer-Williams, 2005).

Memory cells

In primary immune responses, activated B cells differentiate into memory B cells, which are a key cellular component of the protective humoral responses to infectious pathogens. These cells develop within germinal centers of the secondary lymphoid organs. The most important function of memory B cells is to remember the first encounter with invading pathogens, and to provide effective protection against secondary infection for years (Crotty et al., 2003).

Table 2 B cell associated molecules involved in development and differentiation.

<i>Name</i>	<i>Alternative name</i>	<i>Gene family</i>	<i>Function</i>
CD1c	M241, R7, T6	Ig superfamily	Antigen presenting protein
CD1d	R3G1	Ig superfamily	Antigen presenting protein
CD5	Leu-1, T1, Tp67, Ly-1	Scavenger receptor superfamily	Inhibitor of B-cell activation
CD10	CALLA, Nep, MME	Peptidase protein family	Regulates B-cell growth
CD19	B4	Ig superfamily	Regulates B-cell development, activation and differentiation. Signal transduction
CD20	B1, Bp35	Membrane-spanning 4A family	B-cell activation and proliferation
CD21	CR2, EBV-R, C3dR	Regulator of complement activation gene family	Regulator of complement activation, positive regulator B cell activation
CD22	BL-CAM, Siglec-2	Ig superfamily	B-cell adhesion and signal transduction. Inhibitor of B-cell activation
CD23	FcεRII, B6, BLAST-2	C-type lectin family	Low affinity receptor for IgE and key molecule for B-cell activation and growth
CD24	BBA-1, HSA	Sialomucin family	Regulation of B-cell proliferation and maturation
CD25	Tac, p55, IL-2Ra	Cytokine receptor family	Receptor for interleukin-2
CD27	T14, S152, TNFRSF7	Tumor necrosis factor receptor superfamily	Costimulation of B- and T-cell activation
CD30	Ber-H2, Ki-1, TNFRSF8	Tumor necrosis factor receptor superfamily	Activation of NF-κB, apoptosis, autoimmunity
CD32b	FcγRIIB	Ig superfamily	Phagocytosis of immune complexes and regulation of antibody production
CD34	gp10–120, mucosialin, MY10	Sialomucin family	Cell adhesion and possible role in early hematopoiesis
CD38	T10, ADP-ribosyl cyclase	Ectoenzyme family	Cell adhesion and signal transduction
CD40	Bp50, TNFRSF5	Tumor necrosis factor receptor superfamily	Costimulation of B-cell growth. Differentiation and isotype switching
CD45	LCA, T200, B220	Protein tyrosine phosphatase family	Regulator of T- and B-cell antigen receptor signaling; regulator of cell growth and differentiation
CD69	AIM, VEA	C-type lectin family	Lymphocyte proliferation; signal transmission in NK cells and platelets
CD72	Lyb-2	C-type lectin family	B-cell proliferation and differentiation
CD79a	Iga, MB1	Ig superfamily	Subunit of B-cell antigen receptor and signal transduction
CD79b	Igb, B29	Ig superfamily	Subunit of B-cell antigen receptor and signal transduction
CD80	B7, B7-1, BB1	Ig superfamily	Costimulation of T-cell activation and proliferation. Has a critical role in autoimmune, humoral, and transplant responses
CD86	CD28LG2, B70, B7-2	Ig superfamily	Costimulation of T-cell activation and proliferation
CD135	FLT3, FLK2	Ig superfamily	Cell survival, proliferation, and differentiation. CD135 is important for lymphocyte development
CD138	Syndecan-1, B-B4	Syndecan proteoglycan family	Cell proliferation, cell migration, and cell-matrix interactions
CD179a	VPREB1, IGVPB	Ig superfamily	Early B-cell differentiation
CD179b	Λ5	Ig superfamily	B-cell proliferation and differentiation
CD180	RP105, Bgp95	TLR family	Controls B-cell recognition and signaling of LPS
CD267	TACI	Tumor necrosis factor receptor superfamily	Controls T-cell-independent B cell antibody responses, isotype switching, and B cell homeostasis
CD268	BAFF receptor, BR3	Tumor necrosis factor receptor superfamily	The principal receptor required for BAFF-mediated mature B-cell survival
CD269	BCMA, BCM	Tumor necrosis factor receptor superfamily	Promotes B-cell survival
CD272	BTLA	Ig superfamily	Lymphocyte inhibitory receptor, regulates lymphocyte activation and/or homeostasis as well as T-cell tolerance
CD284	TLR4, ARMD10	TLR family	Mediator to innate immunity against bacterial polysaccharides. Induces activation of NFκB and production of type I interferons
CD305	LAIR1	Ig superfamily	Negative regulator of NK, B, and T cells
CD307a	FCRL1, IRTA5	Ig superfamily	B cell activation and differentiation
CD307b	FCRL2, IRTA4	Ig superfamily	B cell activation and differentiation
CD307d	FCRL4, IRTA1	Ig superfamily	B cell activation and differentiation
CD307e	FCRL5, IRTA2	Ig superfamily	B cell activation and differentiation
CD329	SIGLEC9	Ig superfamily	Adhesion molecule that mediates sialic-acid dependent binding to cells. Inhibitor of B-cell activation

The germinal center (GC) is a specialized microstructure that forms in secondary lymphoid tissues, where mature B cells proliferate, differentiate, and mutate their antibody genes. Within the GC, B cells undergo clonal expansion, CSR at the IgH locus, SHM, and selection for increased affinity of a BCR for its unique antigenic epitope through affinity maturation (LeBien and Tedder, 2008). These develop dynamically after activation of FO B cells by the T-dependent antigen.

When foreign antigens/peptides are encountered, naive B cells in the follicle recognize the antigen through BCR and receive signals by binding the peptide to the B cell. Thus, these signals cause the cells to migrate to the edge of the follicle bordering the B-T cell space (Garside et al., 1998). Some of the activated B cells increase Bcl-6 production and migrate back to the follicle and form GCs. The other activated B cells rapidly differentiate into memory B cells in the presence of strong CD40 stimulation from Th cells, before GC formation. These early differentiated memory B cells are gradually replaced by GC-derived memory B cells at later (Weisel and Shlomchik, 2017). First, the GC-independent pathway develops, which rapidly recruits germline-encoded, low-affinity memory B cells. Thereafter, the GC-dependent pathway develops, which takes somatically mutated, affinity matured memory B cells from GC reactions.

Plasma cells

Plasma cells, which are terminally differentiated from activated B cells, produce and secrete large volume of antibodies in response to pathogen infections. Also, plasma cells capable of opsonization and destruction of pathogens are effector cells of humoral immunity.

Mature B cells function as an antigen-presenting cell (APC) when it encounters offending antigens. The antigens are taken up by the B cell through receptor-mediated endocytosis, and hence, antigens are converted into peptides. These peptides are transferred to the cell surface and loaded onto MHC II molecules and then presented to CD4+ T cells on the extracellular surface. Subsequently, as a result of the binding between T cell and MHC II-antigen complex, the B cell is activated. The activated B cell proliferate rapidly and undergo somatic hypermutation.

After activation of the B cell, which usually occurs in GC of secondary lymphoid organs, memory B cells or plasma cells begin to differentiate. Plasma cells have been able to make more powerful properties against the specific antigen by undergoing affinity maturation (Honjo et al., 2004). The activation and growth of B cell clones and ability to secrete antibodies of higher affinity for the specific antigens are known as affinity maturation (Nutt et al., 2015). Thus, the antibodies which are produced and secreted are involved in opsonization, phagocytosis and the eventual destruction of the pathogen.
